- Place a small drop of acrylic glue (cyanoacrylate such as Dermabond or Superglue) on the blunt end of an applicator (e.g., Dacron-tipped applicator, thin paintbrush, curette, straightened paper clip, toothpick, or the wooden end of cotton-tipped swab). Allow the glue to become tacky.
- Quickly, but carefully, touch the glue on the end of the applicator to the foreign body. Establish and maintain contact. Avoid contacting the mucosa en route or pushing the object any farther inward. Hold the applicator still and maintain contact for 30 seconds until the glue hardens.
- Gently pull the applicator out of the orifice with the foreign body stuck to it.

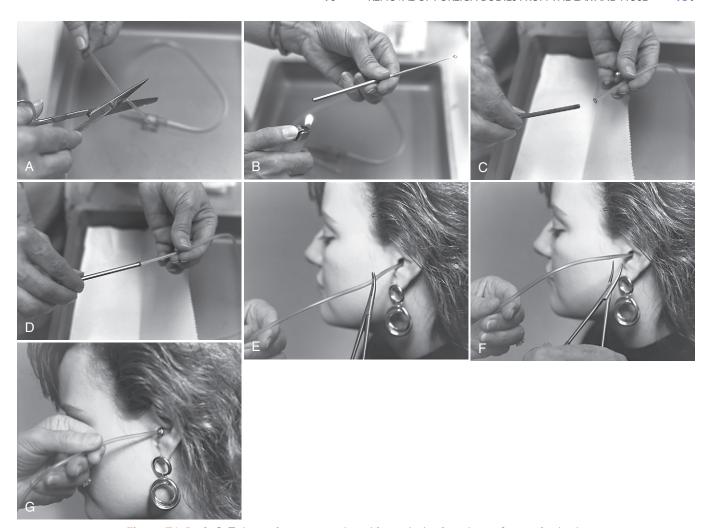

#### **ANESTHESIA FOR AUDITORY CANAL**

For local anesthesia, instill five drops of 2% to 5% lidocaine or 20% benzocaine solution into the canal and allow it to remain for 5 to 10 minutes. Suction to remove fluid and canal debris before injection of a local anesthetic (if needed) under direct visualization. If tympanic membrane rupture is suspected, eardrops and irrigation are contraindicated.

For local field anesthesia of the external half of the auditory canal, inject small amounts (usually <2 mL total) of 1% lidocaine with epinephrine at three or four sites equally spaced along the exterior verge of the canal (see Fig. 76-4). For deeper canal anesthesia (much more sensitive area), subcutaneous injections (0.5 to 1 mL) of plain 2% lidocaine may be considered but is not recommended because the need for multiple injections is usually much more traumatic than the actual foreign body removal. This is especially true for the pediatric population, where in many instances it is more appropriate to use sedation. If subcutaneous injections are used, they are placed in the canal just external to the junction of the cartilaginous and bony canal (approximately one third of the way into the canal). Beginning at the posterior and superior aspect of the canal, use a 27-gauge, 1½-inch needle to slowly infiltrate lidocaine. Repeat this at two or three spots equally spaced around the canal. Allow the lidocaine to dissect down, "blanching" the ear canal and drum, if visible. Topical lidocaine or benzocaine applied to the auditory canal before an injection is often useful. Wait 5 to 10 minutes before instrumentation.

#### **COMPLICATIONS**

- Trauma to mucous membranes (e.g., excoriation, laceration) with the possibility of trauma-related infection or bleeding.
- Injury to a nasal passage, external canal, tympanic membrane, or middle ear.
- Deeper progression of the object leading to the inability to extract in the office.
- Aspiration (nasal passage foreign bodies).
- With delayed or incomplete removal of nasal foreign bodies, the patient may be at risk of obstructive sinusitis and even meningitis from local extension of the sinusitis.

**Figure 76-5** A-G, Technique for removing spherical foreign bodies from the ear. See text for details.

- With foreign bodies of the ear, acute otitis externa is common and may result from injury caused by the foreign body itself or by its removal. Also, when instruments are placed in the ear, the patient may experience bradycardia, or nausea or vomiting (or both).
- Complications of using cyanoacrylate glue include abrading or excoriating the mucosa with the applicator, dripping or spilling the glue on the mucosa, or gluing the applicator to the mucosa. Acetone can be used to remove the glue.

#### POSTPROCEDURE PATIENT EDUCATION

Inform the patient to watch for signs of infection (see Chapter 72, Cerumen Impaction Removal). The patient should follow up with the clinician in 1 to 2 days. He or she should report a headache, fever, or drainage after removal of a foreign body. These symptoms could indicate sinusitis or meningitis or other serious infection. After removal of nasal foreign bodies, the patient should use saline irrigation, two to three times a day for 2 or 3 days. Many clinicians prescribe several days of antibiotic otic drops to prevent external otitis after the mucosa has been possibly abraded, excoriated, or lacerated with irrigation or removal of a foreign body.

#### **PATIENT EDUCATION GUIDES**

See the sample patient education and consent forms online at www. expertconsult.com.

#### **CPT/BILLING CODES**

- 30300 Removal foreign body, intranasal; office type procedure
- 30310 Removal foreign body, intranasal; requiring general anesthesia
- 69200 Removal foreign body from external auditory canal; without general anesthesia
- 69205 Removal foreign body from external auditory canal; with general anesthesia

#### **ICD-9-CM DIAGNOSTIC CODES**

- Foreign body in ear, auditory canal or auricle
- 932 Foreign body in nose, nasal sinus or nostril

#### **ACKNOWLEDGMENT**

### **N**ASOLARYNGOSCOPY

Grant C. Fowler • Rolf O. Montalvo

Fortunately, the incidence and mortality rates for cancers of the oral cavity, pharynx, and larynx have declined slightly over the last 20 years. That said, cancers of the pharynx and larynx remain two of most common cancers in the upper aerodigestive tract, with 12,400 and 12,250 new cases diagnosed, respectively, each year in the United States. Both types of cancer can be diagnosed with nasolaryngoscopy, and the earlier the diagnosis, the better the cure rate. At the same time, the number of nasopharyngeal complaints in the offices of primary care clinicians has increased. For example, sinusitis is now one of the most common chronic diseases in the United States. These facts—combined with the fact that many primary care clinicians have difficulty visualizing the nasal passages, oropharynx, and larvnx—have led many practitioners to seek alternatives to nasolaryngoscopy. Nasolaryngoscopy has now been used for over 30 years. The ease of learning the technique (especially for clinicians already performing endoscopic procedures), its low risk (no need for sedation), the rapidity of the procedure (most procedures can be completed in 10 to 20 minutes), and the relatively low cost of equipment (\$3500 to \$7000) have resulted in increasing numbers of primary care clinicians using this valuable diagnostic tool. In addition, patients appreciate the immediately available diagnostic results, especially when nasolaryngoscopy is performed in the familiar and comfortable environment of their primary care clinician's office. Recent developments include biopsy ports, smaller-diameter scopes, and distal-chip optical systems (improve visualization and may be less prone to fogging). Narrow-band imaging, an image enhancement system, is now available in some models and increases the contrast in the background when visualizing capillaries and veins. This may allow clinicians to diagnose smaller lesions at an earlier stage. In addition, biopsies, dilations, botulinum toxin (Botox) injections, and in-office laser procedures can now be performed through these small-diameter scopes. Although these scopes may in turn be replaced by those capable of performing transnasal esophagoscopy, at present nasolaryngoscopy remains a popular procedure.

The indications for nasolaryngoscopy by primary care clinicians are chronic upper respiratory complaints, especially in smokers or those with unilateral conditions. Nasolaryngoscopy is also helpful in patients with certain acute disorders (e.g., one study found nasolaryngoscopy more effective than sinus films for diagnosing acute maxillary sinusitis). Nasolaryngoscopy is helpful when there is difficulty examining the larynx with an indirect mirror (see Chapter 79, Indirect Mirror Laryngoscopy), such as when there is unusual anatomy or persistent gagging. A large (n = 20,000) ongoing trial in France (Trial of Head and Neck Cancer Screening, THANCS) will attempt to answer whether nasolaryngoscopy combined with esopharyngeal brush biopsy will be effective for screening patients with a history of heavy alcohol consumption and smoking, perhaps decreasing the mortality rate from head and neck cancer.

#### **INDICATIONS**

#### **Chronic Conditions**

- Chronic hoarseness (>3 weeks)
- Chronic sinusitis or sinus discomfort, especially unilateral
- Chronic serous otitis media or eustachian tube dysfunction in an adult, especially unilateral
- Recurrent otalgia
- Suspected neoplasm
- Chronic cough
- Chronic nasal obstruction or postnasal drip
- Chronic rhinorrhea
- Chronic pharyngeal pain
- Halitosis
- Previous head and neck cancer
- Previous conservative treatment of laryngeal polyps
- Head or neck mass or adenopathy
- Recurrent epistaxis
- Dysphagia
- Globus hystericus
- Foreign body sensation in pharynx
- Evaluation of snoring
- Vocal cord paralysis
- Further reassurance against serious disease in any chronic upper respiratory condition, especially in smokers
- Chronic acid (reflux) laryngitis

**NOTE:** More than 60% of patients with reflux laryngitis do not have the classic gastroesophageal symptoms of heartburn and reflux. Instead, they may present with chronic intermittent hoarseness, vocal fatigue, chronic cough, dysphagia, sore throat, stridor, croup, postnasal drip, frequent throat clearing, globus sensation, or a choking sensation. They may also have associated asthma, pulmonary fibrosis, chronic bronchitis, or pneumonia.

#### **Acute Conditions**

- Hemoptysis
- Acute sinusitis
- Acute epistaxis (without profuse hemorrhage)
- Suspected nasal foreign body
- Suspected laryngeal foreign body
- Acute onset of hoarseness after straining voice

#### **CONTRAINDICATIONS**

- Acute epiglottitis (may precipitate complete airway obstruction)
- Acute epistaxis (bleeding source may be difficult to visualize with profuse hemorrhage)

- Uncooperative patient
- Facial fractures, especially midface, or basilar skull fractures with possible cribriform plate injuries (relative contraindication, orolaryngoscopy may be a better option, but see text regarding a bite block)
- Recent nasal or oropharyngeal surgery (may be relative contraindication, depending on nature and location of the surgery)

#### **EOUIPMENT**

• Flexible nasolaryngoscope with light source. Like recently manufactured gastroscopes and colonoscopes, newer nasolaryngoscopes are available with distal-chip digital optical systems (i.e., camera at the tip) where the cameras have basically replaced the fiber-optic technology. However, fiberoptic nasolaryngoscopes are still manufactured and tend to be less expensive. Recently manufactured scopes (both fiberoptic and distal-chip) are also completely immersible, which simplifies cleaning and disinfection. Frequently, light sources used for other endoscopes in the office may be adaptable to a nasolaryngoscope. This might be an important consideration when purchasing a flexible sigmoidoscope, gastroscope, or colonoscope.

**NOTE:** Although distal-chip technology improves visualization enough in colonoscopy to sometimes overcome an inadequate preparation, thereby allowing the clinician to complete a procedure that might be impossible with a fiberoptic scope (the lens in fiberoptic scopes is more easily occluded by stool when the prep is poor), there is no preparation necessary with nasolaryngoscopy. Therefore, there is less need to increase the cost by upgrading to distal-chip from fiberoptic technology for nasolaryngoscopy.

- Nasal speculum
- Sterilizing solution, such as glutaraldehyde (Cidex)
- Decongestant\*: phenylephrine (0.25% to 2%) spray (Neo-Synephrine, Vicks) or epinephrine 1:50,000 (Adrenalin) or oxymetazoline hydrochloride 0.05% spray (Afrin, Neo-Synephrine 12 hour)
- Anesthetic: lidocaine (2% to 5%) solution in an atomizer spray bottle or benzocaine spray (14%) (Cetacaine)<sup>†</sup>
- Goggles, mask, and gloves (equipment necessary to follow universal blood and body fluid precautions)
- Optional supplies include cotton balls or pledgets soaked in either a decongestant or anesthetic. Three ear, nose, and throat spuds with soaked cotton applicators are another option. Cocaine solution (4% to 10%) can be used for both decongestion and anesthesia. At this strength, it does not produce a euphoric effect; however, many clinicians choose not to stock cocaine because of the mandatory record keeping and the risk of burglary. If cocaine is considered for the anesthetic, patients should be informed of the risk of finding its metabolites in their urine in case they have on-the-job drug screening.

#### PREPROCEDURE PATIENT EDUCATION

After explaining the procedure, inform the patient that he or she may experience an intense tickling sensation on insertion of the scope. Warning the patient beforehand can minimize his or her response. Use of a topical decongestant or an anesthetic may decrease this sensation. Although nasolaryngoscopy can be performed without these, visualization and patient tolerance are usually improved with their use. This may be especially helpful with inexperienced operators or anxious patients. The patient should be

informed if a decongestant or anesthetic will be used. Next, the objectives of the procedure should be described carefully. Explain to the patient that he or she may speak during the procedure, and that you should be told if the patient is having any significant discomfort other than pressure. The patient will be asked to say certain words or sounds and may be asked to swallow or to avoid swallowing at different stages. The patient should keep his or her eyes open and focused straight ahead to minimize the gag reflex. Breath holding can also trigger the gag reflex, so the patient should be encouraged to breathe through the mouth.

#### **TECHNIQUE**

- 1. Before performing the procedure, a thorough head and neck history and examination, as well as the remainder of a complete history and physical examination, should be performed. The procedure is brief enough to be performed on the initial visit. If nasolaryngoscopy is not performed on the initial visit, when the patient returns obtain the interval history and again examine the head and neck. Explain the procedure again.
- 2. Before applying decongestant or anesthetic, the patient should be asked to gently blow his or her nose to clear the nasal passage. Give the patient some tissues to hold in one hand and a plastic emesis basin in the other. The patient should have an absorbent sheet draped over the shoulders that is then tucked inside the collar. The clinician should follow universal blood and body fluid precautions.
- 3. With the patient sitting up, apply decongestant generously by spraying the atomized solution into both nostrils. If the same spray nozzle is to be used with another patient, it should not touch him or her. One spray should be directed superiorly and a second posteriorly. After spraying, have the patient tilt his or her head back to allow the liquid to drain as far back as possible. The patient should then swallow any residual. Unless both nares need to be intubated, determine by visual inspection which nostril is the least obstructed. After decongestion, this is the nostril that should be anesthetized for scope insertion.
- 4. After waiting 5 to 10 minutes for the decongestant to take effect, anesthetize the nostril(s) chosen for scope insertion. Spray liberal amounts of lidocaine or benzocaine aerosol spray; direct the spray superiorly for 1 second and then posteriorly for about 1 second with the patient tilting his or her head back and again swallowing any residual. The patient should be warned that lidocaine has a sour taste. Swallowing the anesthetic assists with suppression of the gag reflex. For patients with a hyperactive gag reflex, gargles with lidocaine solution or a generous spraying of the pharynx with benzocaine may be helpful. The patient is ready for the procedure when he or she reports a lack of sensation at the back of the throat.

As an alternative to spraying, soaked cotton balls or pledgets can be inserted with offset or bayonet forceps through the nasal speculum. One cotton ball (or pledget) should be inserted superiorly, another inserted in the middle meatus, and a third posteriorly. They should remain in place for 5 to 10 minutes and then removed before insertion of the scope. Three ENT spuds with cotton applicators can be used in the same manner. If cotton balls, pledgets, or spuds are used, the back of the pharynx should also be sprayed with anesthetic to suppress the gag reflex.

5. Before insertion of the scope and while waiting for the anesthesia to take effect, the clinician may want to become reacquainted with the scope (for those who do not regularly perform endoscopic procedures). Deflect the tip both ways to observe which direction and how far it moves for a given movement of the deflector. The focal length on most scopes is about 5 mm or greater, and viewing an object through the scope (e.g., a penny, a piece of gauze) before insertion may give the clinician a better sense of distance and magnification. In general, as it is advanced, the tip of the scope moves toward whatever structure is directly

<sup>\*</sup>Should be used with caution in those who are severely hypertensive or have a history of sensitivity to the agent.

<sup>&</sup>lt;sup>†</sup>Should be used with caution in those who have a history of an allergy or sensitivity to the agent.

in the center of the field of view. Note that for these very small scopes, a slight deflection of the tip can cause a marked change in direction of the scope. It should also be noted that the most difficult aspect of nasolaryngoscopy may not be manipulating the scope, but rather maintaining familiarity with the complex anatomy of the nose and throat. Clinicians who do not frequently perform the procedure may benefit from a brief review of the anatomy before each procedure. Atlases and CD-ROMs/DVDs are available for such reviews (see the "Bibliography" section).

- 6. Place the patient in either an erect (sitting) or supine position. Both examiner and patient should be in a position that they can maintain comfortably for 20 minutes. The patient is reasonably protected from injury caused by his or her own sudden movements or by jumping away from the scope if in the supine position. Patients who are sitting can be protected by placing their head all the way back against a high, firm headrest. A small child may want to sit in a parent's lap; the parent should then hold the child firmly, especially the head, to help protect from any injury that might be caused by sudden involuntary movements.
- 7. Rest the hand you will be using to guide the endoscope on the patient's cheek. Your middle, ring, and little fingers should form a tripod to support the index finger and thumb while handling and guiding the tip of the scope. As you gain more experience, you may wish to rest this tripod on the patient's forehead to sense for tensing of the frontalis muscle, which is often the first sign that the patient is experiencing significant discomfort. Turn on the light source. Tell the patient to close his or her eyes and to expect a bright light and possibly a tickling sensation. Insert the tip through the least-obstructed nostril and past the nasal hairs at the vestibule. If the scope is prone to becoming fogged, rest it against the nasal septum to warm it. Warming the scope usually defogs it.
- 8. The floor of the nasal cavity, which is in the inferior meatus, usually offers the most open channel and the best passage for intubations (Fig. 77-1). (The meatus is the space below each turbinate.) Advance the scope only toward visualized objects; avoid advancing the scope blindly or against significant resistance. As with other endoscopic procedures, if only white is visible (a "whiteout"), the scope is probably resting against mucosa and should be withdrawn until the actual structure that the mucosa is covering is visualized. A deviated septum or large maxillary ridge may impede advancement of the endoscope along the floor. In this situation, make an attempt to pass the scope through the middle meatus, keeping in mind that the patient usually experiences discomfort whenever the scope is directed or advanced superiorly. If this is unsuccessful, withdraw the scope and intubate the other nostril.

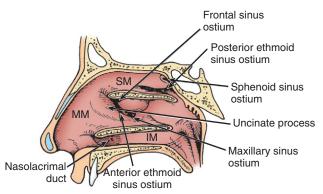

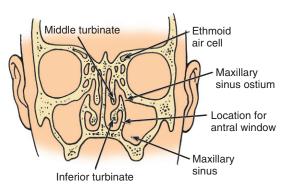

Figure 77-1 Sagittal section of the head with the turbinates removed to demonstrate ostia of the paranasal sinuses and the nasolacrimal duct. IM, inferior meatus; MM, middle meatus; SM, superior meatus.

**NOTE:** If unable to intubate either nostril, after spraying the back of the pharynx with benzocaine to suppress the gag reflex, the scope can be passed through the oropharynx. In this situation, the patient might damage the scope by biting it. To minimize this risk, the barrel of a 10-mL syringe (minus the plunger) can be cut in half (cut crosswise or across the diameter), and the remaining barrel placed between the patient's upper and lower front incisors. If the scope is then inserted through the barrel, it should serve as a bite-block.

- 9. As the scope is advanced along the floor, the feet of the medial crura (of the lower lateral septal cartilages) can frequently be seen protruding from the medial aspect of the nasal passage. The inferior turbinate is visualized about 1 cm into the passage. Note the texture and size of the inferior turbinate, as well as any polypoid degeneration or any swelling of the covering mucosal membranes. Flexion of the scope slightly upward often illuminates the middle turbinate in the distance and its meatus. The nasolacrimal duct drains into the inferior meatus and is usually not seen; however, purulent fluid draining from it is evidence of a nasolacrimal gland infection. If the patient has had surgical antral windows placed into the maxillary sinus, the openings are frequently located in the inferior meatus. These openings can often be entered with a scope (Fig. 77-2). Note the condition of the mucosa if the antral windows are entered.
- 10. Next, pass the scope posteriorly about 4 to 5 cm until the choana comes into view. The choana is the junction between the nasal fossa and the nasopharynx, and it looks just like a posterior "nostril." It should form a halo in front of adenoid tissue. If desired, move the scope laterally and superiorly to allow entry into the middle meatus. However, because superior reflection of the scope may result in discomfort to the patient, it may be prudent to examine the middle meatus on the way out after visualizing the larynx. Again, if the nasal floor is obstructed, there may be no choice but to attempt passage of the scope through the middle meatus.
- 11. On entering the choana, the adenoid pad appears on the posterior wall of the pharynx. Star-shaped scarring may be all that is seen if the patient has had an adenoidectomy. Advance the endoscope into the nasopharynx, and when the posterior margin of the septum is passed (when it is no longer seen), slightly flex the tip of the endoscope and rotate 90 degrees laterally to observe the torus tubarius. The torus is the valve at the opening of the eustachian tube (Fig. 77-3). Ask the patient to say "key, key, key" while you observe valve function. The eustachian tube should open and close slightly. Adenoid or lymphoid hyperplasia may be noted in this area or elsewhere throughout the procedure. It may actually block the torus tubarius. By advancing the scope slightly and rotating 180 degrees

**Figure 77-2** Frontal section of the head. In this section, eight ethmoid air cells (four on each side) are shown in their locations medial to the orbit. A rather large maxillary sinus ostium is demonstrated, as well as the location in the inferior meatus for surgical placement of antral windows.

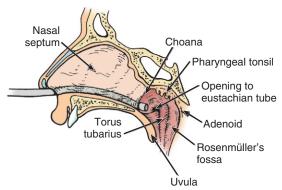

Figure 77-3 Anatomy of nasopharynx and oropharynx.

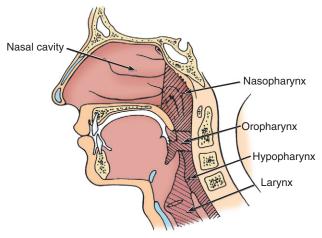

while avoiding the septum (make sure to avoid contacting the septum!), the opposite torus is illuminated. Its function should also be observed. Purulent fluid may be seen draining from a eustachian tube and should be noted. Posterior to both tori and anterior to the adenoid pad lie the clefts of Rosenmüller, each of which should be carefully inspected. Most nasopharyngeal malignancies are found in this area.

12. Next, advance the scope inferiorly and toward the posterior wall of the oropharynx (Fig. 77-4).

**NOTE:** If possible, avoid touching the posterior pharynx or the base of the tongue, which may elicit the gag reflex.

Instruct the patient to breathe through his or her nose to keep the soft palate from obstructing the view. As the patient swallows or talks, the normal movement of the soft palate can be seen. Downward flexion and slight rotation of the scope as it nears the posterior wall will allow for inspection of the uvula, the soft palate, and the lateral and posterior walls of the pharynx. The epiglottis should be seen in the distance. Note the presence of any masses, scarring, inflammation, exudate, mucosal irregularities, or pulsations. In some cases, dysphagia may be explained by lymphoid hyperplasia in this area, especially if the hyperplasia is associated with enlarged palatine tonsils and an exudate.

13. When the scope has passed the soft palate, it enters the oropharynx. Again, for the remainder of the procedure, attempt to avoid touching the posterior pharynx while keeping the scope as close as possible to it. If the scope becomes fogged, tell the patient to swallow; this often clears the scope. With slight flexion and rotation, examine the posterior tongue, lingual tonsils, palatine tonsils, epiglottis, and medial and lateral glos-

**Figure 77-4** Anatomic divisions of the upper airway. All five divisions may be inspected with a fiberoptic nasolaryngoscope.

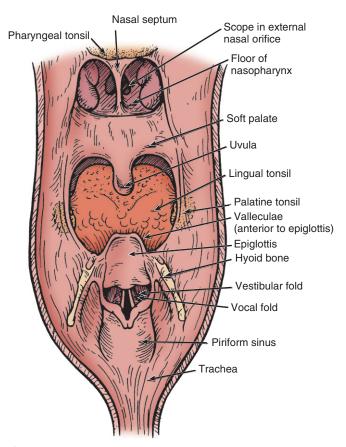

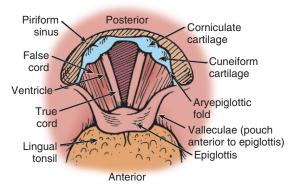

Figure 77-5 Oropharyngeal and laryngeal areas, viewed from posterior.

soepiglottic folds. Avoid touching the base of the tongue, which can trigger the gag reflex. Examine the valleculae from above (Figs. 77-5 and 77-6). Ask the patient to stick out his or her tongue to improve visualization of the valleculae.

14. When the scope has passed the epiglottis, it enters the hypopharynx (see Fig. 77-4). Ask the patient to refrain from swallowing; at this level, swallowing can induce an unusual foreign body sensation or provoke coughing. Assure the patient that if it is unavoidable, it is all right to swallow; however, he or she may experience the sensation of swallowing the scope. If this sensation becomes too strong, the scope may be withdrawn until the sensation passes. The arytenoid cartilages, the corniculate and cuneiform cartilages, and the aryepiglottic folds can be visualized at this level. The piriform sinuses posterior to the cords should be at least partially inspected. Closely examine the

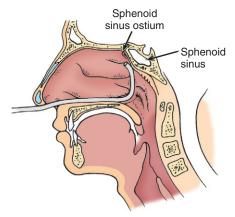

**Figure 77-6** Larynx viewed from above and oriented as it would be seen with a fiberoptic nasolaryngoscope.

false and true vocal cords and the ventricles during quiet respiration (see Fig. 77-6). Tell the patient to hold a prolonged high "eee" sound while you watch for symmetry of cord mobility as well as edema, hemorrhages, erythema, nodules, or masses of the cords or surrounding structures. Record any mucosal or structural abnormalities.

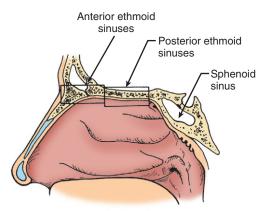

Vocal cord nodules, cysts, and polyps usually occur at the junction of the anterior and middle third of the cord. Nodules are generally caused by vocal abuse and are usually bilateral, small, white, sessile, and firm. Vocal cord cysts are usually unilateral and filled with caseous material, and can be due to vocal abuse (i.e., epidermoid). Mucous retention cysts are also usually unilateral due to an obstructed duct and filled with mucoid material. Polyps are also caused by vocal abuse, are usually unilateral, and can be sessile or pedunculated with a prominent feeding vessel on the superior aspect of the vocal cord. There may be evidence of preceding hemorrhage. Reinke's edema, also known as polypoid degeneration of the vocal cords, appears as sausage-shaped edematous vocal cords. It is usually due to tobacco abuse, but can also be at least partly due to vocal abuse and gastroesophageal reflux disease. Other findings associated with reflux larvngitis can be diffuse or limited to the vocal cords. The ventricles can be obliterated, the arytenoids thickened, and there may be erythema, edema, or "cobblestoning" of the posterior aspect of the larynx or trachea.

**NOTE:** The scope should *never* touch or pass below the cords. When nearing the cords, if the patient accidentally swallows, the operator should be prepared to quickly withdraw the scope enough to avoid touching them. If the cords are touched, severe laryngospasm can occur with resultant patient asphyxia.

15. Next, withdraw the scope to a position just anterior to the choana and direct it very superiorly, almost inverted on itself (Fig. 77-7). With the tip in this position, carefully withdraw the scope slightly again, and the sphenoid bone should appear. (The sphenoid bone will appear in what was previously an inferior position in scope orientation, before inversion.) The superior turbinate may be seen, as might an anatomic variant, the supreme turbinate—should be visible. The sphenoid sinus, which can be thought of as a large posterior ethmoid air cell (Fig. 77-8), is usually the only sinus in the posterior ethmoid group with a visible ostium (see Fig. 77-1). Again, care is necessary when directing the scope superiorly. This is an area where anesthesia is frequently incomplete, and this maneuver may cause the patient some discomfort.

**Figure 77-7** Nasolaryngoscope is withdrawn to a position just anterior to the choana and retroflexed.

**Figure 77-8** Parasagittal section of the head showing the relationship of the anterior and posterior ethmoid sinuses. The bone in this area is eggshell thin.

16. Straighten the scope and withdraw to the level where the complete choana comes into view. Move the scope in a superior and lateral direction to allow examination of the middle meatus. In most cases it is easier to examine the middle meatus from posterior to anterior. The frontal sinus, anterior ethmoid cells, and maxillary sinus ostia are located in the middle meatus, with the maxillary sinus ostia the most likely to be visualized. Observe for any drainage from ostia.

**NOTE:** Drainage of pus from an ostium is diagnostic of acute sinusitis, with accuracy possibly greater than radiographs.

Inflammation should be recorded, and attempts should be made to identify the source of any purulent fluid or polyps protruding from or occluding the ostia. The majority of polyps are seen in the middle meatus, originating from the anterior ethmoid cells. Typical polyps are slightly yellow, translucent, and relatively avascular. They can originate from nasal mucosa (most common) or they can result from polypoid degeneration of a turbinate. Polyps can be filled with mucus or fluid. Frequently they have a stalk, or extension of mucosa, that can be traced back to their sinus of origin. Through air drying and subsequent keratinization, polyps can develop benign squamous metaplastic changes, becoming more opacified and whiter or grayer in appearance.

17. On completion of the examination, withdraw the scope and explore the opposite nasal cavity, if indicated.

NOTE: As with any endoscopic procedure, the natural tendency during nasolaryngoscopy is for the examiner to move toward whatever is being visualized. This action may form a tight loop in the scope outside the patient's nose. Such a tight loop may actually break the scope or the fibers in the scope (if a fiberoptic scope). To prevent this tendency, remember to relax and maintain the same distance from the patient throughout the procedure. If you straighten the scope at the end of the procedure before removing it from the patient's nose, the patient is usually grateful.

#### **CARE AND CLEANING OF EQUIPMENT**

Although nasolaryngoscopes are fairly indestructible, they are composed of fibers/lenses or cameras that can be broken; hence, avoid bending the scope into tight angles (especially a fiberoptic scope) or traumatizing the tip. Wash the scope with soap and water between procedures, and then soak it for 10 minutes in glutaraldehyde. Make sure the glutaraldehyde is thoroughly rinsed from the scope, before air drying, to prevent chemically irritating the next patient's mucosa. Clean the lens with lens cleaner and paper.

#### **COMPLICATIONS**

- An adverse reaction to anesthetic or decongestant (most common)
- Sneezing and gagging severe enough to prevent completion of the procedure
- Laryngospasm with possible asphyxia; prevented by remaining above the level of the vocal cords
- Blood pressure elevation (very rare and usually related to an adverse drug reaction)
- Vasovagal reaction (rare)
- Epistaxis (it is possible to dislodge eschar or to traumatize a tumor)
- Vomiting with possible aspiration

#### **CPT/BILLING CODES**

### MANAGEMENT OF EPISTAXIS

Scott Savage

Nosebleed is a common complaint with an incidence of approximately 1 per 1000 patients annually in the United States. Ninety percent of nosebleeds resolve, either spontaneously, with the aid of pinching the outer soft tissue of the nose (Fig. 78-1), or by applying an ice pack to the bridge (Fig. 78-2). Managing the other 10% is the topic of this chapter.

The most common cause of minor nosebleed is dry nasal mucosa (i.e., low-humidity environment such as in the desert or in a cold climate where heating is used). Moderate nosebleed is usually caused by nasal trauma; severe nosebleed is often a complication of a medical condition such as a coagulopathy caused by medications, cancer, or cirrhosis. Although hypertension is often seen in patients with nosebleeds, studies have been unable to confirm this condition as a cause. Rather, it appears that nosebleeds are associated with anxiety, and anxiety leads to hypertension. Localized causes of nosebleeds also include inflammation from colds and allergies, foreign bodies, nasal septum deformities, and sinonasal neoplasms. Systemic causes include coagulopathies, Osler-Weber-Rendu disease (hereditary hemorrhagic telangiectasia), and use of nonsteroidal antiinflammatory drugs or anticoagulants. Osler-Weber-Rendu disease is an autosomal dominant condition in which the vascular walls lack contractile elements; consequently, prolonged and heavy bleeding can occur despite a normal coagulation profile. The diagnosis can be suspected when there is a family history compatible with the disease.

Nosebleeds can be divided into three groups: anterior, posterior, and mixed. Anterior bleeds account for approximately 90% of epistaxis. Posterior and mixed bleeds can be clinically suspected in patients who have brisk, bilateral, nontraumatic bleeding that does not abate with anterior packing. Posterior bleeding can be lifethreatening and is more common in patients older than 40 years of age. Usually the patient can tell you which side of the nose started bleeding. With posterior bleeding, blood also usually runs down the back of the throat.

Understanding the anatomy of the nasal cavity is useful for obtaining efficient and effective control of bleeding. The blood supply for the nasal septum arises from both the internal and external carotid arteries. A primary source for the posteroinferior septum is the sphenopalatine artery, a branch of the internal maxillary artery, which in turn is a branch of the external carotid system. The uppermost part of the nasal septum is supplied by the anterior and posterior ethmoid arteries, which arise indirectly from the internal carotid system. The blood supply for the anterior nasal septum is the superior labial artery, which is also indirectly a branch of the internal carotid system. All of these arteries anastomose in the anterior central portion of the nasal septum, an area known as Kiesselbach's plexus (Fig. 78-3). It is estimated that 95% of anterior nasal bleeds occur there. An occasional source of anterior bleeding is an exposed edge from a perforated nasal septum. Anterior bleeding from the lateral nasal cavity is rare, although telangiectases from Osler-Weber-Rendu disease can be seen here. Trauma can also result in lateral bleeding.

The clinician treating epistaxis must understand the normal anatomy of the nose and be familiar with the nasal septum and its appropriate midline position. He or she should be able to identify the inferior and middle turbinates. With an understanding of normal anatomy, when a patient has a nosebleed, the examiner should quickly notice if there are any anatomic abnormalities (e.g., deviated nasal septum, a nasal polyp, a mass). Bleeding is not unusual on either side of a deviated nasal septum.

#### **INDICATIONS**

- Nosebleed lasting longer than 10 minutes despite pinching outer nasal tissue or application of ice
- Recurrent nosebleeds despite treatment
- Traumatic nosebleed with suspected nasal fracture
- Nosebleed associated with a septal perforation or other nasal abnormality
- Nosebleed in patient with high-risk medical condition
- Nosebleed in frail patient

#### **CONTRAINDICATIONS (RELATIVE)**

- Patients with advanced chronic obstructive pulmonary disease (COPD) or other advanced cardiac or pulmonary conditions (nasal packing can induce the nasopulmonary reflex, causing the arterial oxygen pressure to drop by as much as 15 mm Hg).
- Untreated coagulopathy, a displaced fracture, or Osler-Weber-Rendu disease (nasal packing can disrupt friable tissue, especially posterior packing, and should be done with caution in these patients; attempts should be made to normalize clotting factors, if possible, before instrumentation).
- Other critical conditions, such as a threatened airway or other problem that should be managed first, may mandate a delay in managing a nosebleed.

#### **EQUIPMENT**

Preparing a "nosebleed tray" in advance is useful.

- Headlight
- Tongue depressor
- Yankauer suction catheter
- Frazier suction catheters, no. 5 and no. 7
- Nasal speculums, short and medium length
- Bayonet or offset forceps (see Chapter 76, Removal of Foreign Bodies from the Ear and Nose, Fig. 76-1)
- Fine Adson forceps
- Emesis (kidney) basin
- Cotton balls
- Cotton-tipped swabs (wooden handle preferred if applying Gelfoam or Surgicel)

Figure 78-I Apply pressure by pinching the nose to stop the bleeding.

Figure 78-2 An ice pack can be applied to the bridge of the nose.

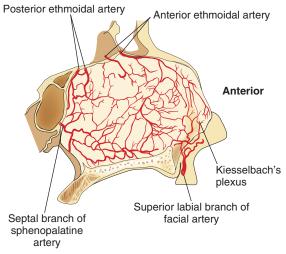

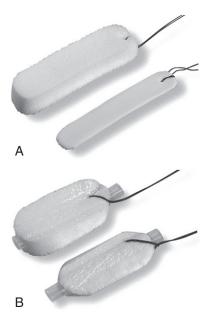

Figure 78-3 Anatomy of the septal blood supply.

**Figure 78-5** Rhino Rocket nasal sponge system. (Courtesy of Shippert Medical Technologies, Centennial, Colo.)

**Figure 78-6** Nasal balloon device. The *Medtronic Xomed EpiStat I* (pictured) is a double (anterior and posterior) balloon catheter. The *EpiStat II* is a posterior balloon catheter with anterior soft packing attached. It also contains an airway and can be used for bleeding from an indeterminate site, whether posterior, anterior, or both. If posterior bleeding stops, the balloon catheter and airway can be removed, leaving the anterior packing in place. (Courtesy of Medtronic Xomed ENT, Inc., Jacksonville, Fla.)

- Gelfoam or Surgicel (Surgicel may be better for coagulation but may delay healing, so it is often reserved for when Gelfoam is not effective or available)
- 4 × 4 gauze sponges
- Silver nitrate sticks
- Petroleum impregnated gauze, ½-inch wide, up to 72 inches long
- Nasal sponges/tampons (Fig. 78-4) or Rhino Rocket (Fig. 78-5)
- Nasal balloon devices (Fig. 78-6)
- 12- to 14-Fr Foley catheter with 30-mL balloon, umbilical clamp and padding
- Red rubber (in and out or Robinson) soft catheter(s)
- Bite block
- 3-inch dental gauze roll
- Umbilical tape or heavy silk (nonabsorbable) sutures, two pieces at least 18 inches long each
- Petroleum jelly (Vaseline) or other lubricant
- Phenylephrine 2% or oxymetazoline 0.05%
- Epinephrine 1:1000
- Local anesthetic such as lidocaine 2% to 5%, benzocaine 14% spray or 20% solution, or tetracaine 2%
- Gowns, gloves, and face shield as necessary for clinician to follow universal blood and body fluid precautions
- Chux or towels

#### PREPROCEDURE PATIENT EDUCATION

The patient or guardian should know about the risks (as listed in the Complications section), benefits, and any options for the procedure as well as the procedure itself. Obtain written informed consent if the patient's condition allows (see consent form online at www.expertconsult.com). Warn the patient that the procedure may be painful, especially initially, but that everything possible will be done to minimize the discomfort. If the patient is stable, a mild narcotic or sedative may be helpful, especially for posterior packing.

#### **TECHNIQUE**

#### **Patient and Clinician Preparation**

- 1. Obtain vital signs and address any significant vital sign abnormalities. Apply pulse oximetry (vasoactive drugs will be used; packing can provoke the nasopulmonary reflex with subsequent decreases in oxygen saturation).
- 2. Have the patient sit back on a procedural chair or gurney with the head elevated approximately 45 degrees. Gown and drape the patient appropriately; the patient can also be given an emesis basin. While getting the patient positioned, ask which side started bleeding first and which side is currently bleeding the most. Have the patient continue to apply ice or pressure while the equipment is being assembled.
- 3. Connect the suction tubing and catheters to wall suction. Don the headlamp. *Good lighting is critical to the procedure.*
- 4. Inspect the oropharynx for trauma, or any other abnormality. Plan to inspect the nasal cavity that is not actively bleeding first. If both are bleeding, and the patient cannot state which side started bleeding first, inspect the side of the patient's dominant hand. Many nosebleeds are caused by nose-picking, and people are less clumsy with their dominant hands. This side will generally be easier to examine.
- 5. Have the patient blow his or her nose gently to remove any loose clots that may obstruct the examination. Insert the short nasal speculum and open it vertically. Suction any blood or clots and inspect the nasal cavity, specifically looking at the floor, vestibule, turbinates, and septum. Forceps may be helpful for manual removal of large clots.

**NOTE:** If you are able to get behind the source of the bleeding with the suction tip, the condition can be managed in the office.

- 6. Vasoconstrict and anesthetize the nasal mucosa using appropriate agents. If using separate agents for these purposes, apply the anesthetic first unless bleeding is so rapid that the anesthetic is likely to be washed out before being effective. Having the patient sniff an aerosolized solution is the easiest way. If time allows, best results are obtained if the anesthetic has been in place at least 15 minutes.
- Alternatively, pledgets soaked with an agent can be applied. Monitor the patient's vital signs when using vasoconstrictive agents.

**NOTE:** The offset forceps can be used to make a pledget. First, flatten and grasp with the forceps most of the length of an appropriate amount of cotton pulled from a cotton ball. Next, grasp the opposite end of the cotton with the other hand, and while holding this end, twirl the forceps to twist the cotton in and around the long blades. Finally, relax the forceps and slip the pledget off the end. It is now ready to be soaked and inserted.

#### **Absorbable Dressings**

Although several types of absorbable dressings are now available, the two most commonly used are still Gelfoam and Surgicel. These dressings form a scaffold for the formation of a blood clot. Although Surgicel may be better for stimulating coagulation, it is more expensive and may delay healing; therefore, Gelfoam is usually preferred. Surgicel is often reserved for when Gelfoam is not effective or available. These dressings may be used as a primary technique for discrete bleeding, as a bandage over a previously cauterized site, or as a mucosal sheet over an area of diffuse bleeding (e.g., coagulopathy) before packing is applied. If these are in place before packing is removed, it may prevent the clot from being dislodged.

- When applying these dressings it is helpful to use forceps and a
  cotton-tipped swab stick with a wooden handle to manipulate
  the dressing, to press it onto the bleeding site, and especially to
  hold it down when releasing the forceps so the dressing does not
  dislodge.
- Before using the swab stick, remove about half of the cotton to make it small enough to be useful, and moisten the tip with saline or tap water to prevent the dressing from sticking to it.

#### **Cauterization**

Cauterization is suitable for discrete areas of bleeding in the anterior nares. The preferred method is to use silver nitrate sticks, which are especially useful in children. Do not perform cautery at the same location on both sides of the septum because it may interrupt the entire blood supply to the septum, resulting in damage or necrosis. Electrocautery should be done only by an experienced operator because damage to the septal cartilage may occur.

- First, suction the nares and keep a small Frazier suction catheter ready to suction excessive blood. Attempt to dry the surrounding mucosa with a dry cotton swab; this will not only make the silver nitrate more effective, it will also minimize spread beyond the area.
- 2. Apply the silver nitrate stick with gentle pressure for 3 to 10 seconds. Do not use the stick for more than 10 seconds in any area or septal cartilage may be damaged. Do not cauterize an area greater than 1 cm in diameter, which is equivalent to about four dabs of the stick if only the bulb portion is used. As mentioned previously, do not cauterize both sides of the septum at the same location. Silver nitrate causes a burning sensation, so the patient will appreciate having the anesthetic in place for at least 15 minutes. Some authors apply the silver nitrate peripherally (approximately 0.5 cm from site) and in a circular motion around the offending area or vessel. They then gradually move toward

the center of the site until the bleeding stops. Electrocautery should be applied in the same manner. Some clinicians apply electrocautery directly down the Frazier suction tip by touching it with the cautery unit.

- 3. After hemostasis is obtained, use Gelfoam, Surgicel, or an equivalent specialized dressing to protect the cauterization site. If these are not available, use a small amount of petroleum jelly and gently place it on the cautery site.
- 4. Antibiotic therapy is considered optional in these cases. If cauterization fails, consider the use of packing or a balloon device.

#### **Expandable Nasal Sponge and Tampon Packing**

This technique is generally easy and effective in mild to moderate anterior bleeding. The sponges/tampons come in a variety of sizes and shapes, and the 4- to 6-cm sizes are usually ideal (see Fig. 78-4). They are initially rigid, but soften when saline or tap water is applied or blood is absorbed.

- 1. Prepare the sponge/tampon by opening the package and removing the string (the string is not necessary and is usually irritating to the patient). If necessary, trim the sponge to a size and shape that appears consistent with the patient's nasal opening, usually about 4 to 6 cm in length. An exact fit is not required, but using a wide, 10-cm-long sponge in a small patient is uncomfortable, unnecessary, and more difficult to remove. Likewise, if only a small sponge is available, and the patient has a large nasal opening, then consider using two sponges side by side. When cutting the sponge, make sure to avoid leaving any corners or other sharp edges.
- 2. Coat all but the distal tip of the sponge in petroleum jelly to avoid premature softening of the sponge. Use of an antibiotic ointment is more expensive, not necessary, and not beneficial to the patient; the antibacterial activity lasts only 2 to 4 hours. If using the Rhino Rocket (see Fig. 78-5), remove the sponge from the syringe-like device before inserting it. The syringe can generate enough force to damage the nasal mucosa, septum, or other structures.
- 3. Insert the sponge in a smooth motion, entering in a near vertical direction, and then rotating it to a horizontal direction. Continue passing the sponge along the inferior nasal floor until it is completely inside the nasal passage. When in place, the trailing tip of the sponge should be visible inside the nostril but not protruding from it.
- 4. Slowly drip about 2 mL of saline or tap water onto the tip to help the sponge expand more quickly.
- 5. Closely monitor the patient for 3 to 5 minutes for complications and to see if the technique was adequate to abate the bleeding. Keep the patient in observation status for approximately 30 minutes after completing the packing.
- 6. If successful, packing should be left in place for 48 hours and the patient should be placed on oral antibiotics. Persistent bleeding may be due to a bowed septum; inserting the same size sponge on the contralateral side may halt bleeding. If bleeding persists, choices include removing the sponge to insert a larger sponge or two smaller sponges or proceeding to anterior packing or insertion of a nasal balloon (see Fig. 78-6).

#### **Anterior Packing**

Packing is a time-consuming process, but is a viable alternative where there is diffuse bleeding but a nasal sponge/tampon is either unavailable or insufficient.

 Because of the amount of discomfort caused by this technique, it is generally advisable to give the patient a narcotic or sedative medication, or both, unless a contraindication exists. If using a combination analgesic, take caution to use one that does not increase bleeding.

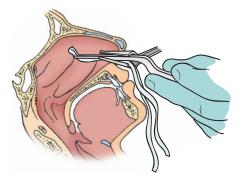

Figure 78-7 Insert anterior pack with folded end inserted first.

- 2. Fold a ½- by 72-inch piece of petrolatum gauze in half. Using bayonet forceps, place the center-folded end (not the free end) into the nostril (Fig. 78-7). Make sure the gauze is placed back all the way to the posterior soft tissue.
- 3. Pat down the gauze, and continue to layer it in an accordion fashion, patting down each layer. Gauze should be layered from nasal floor to turbinates (Fig. 78-8). Approximately 4 to 5 feet of gauze will be required.
- Leave at least an inch of gauze protruding from the nostril. This should be taped to the patient's cheek to avoid inadvertent removal.
- 5. If successful, leave the packing in place for 48 hours. Also place the patient on antibiotics. If this incompletely stops the bleeding, then packing the contralateral nostril in a similar fashion may buttress the original dressing by preventing bowing of the septum. If bleeding persists, choices include removing the packing to insert an anterior nasal balloon, a posterior balloon, or posterior packing.

#### **Balloon Tamponade**

These devices are fast and easy to place. They come in several sizes, shapes, and configurations (e.g., single-balloon, dual-balloon). The most versatile device is the dual-balloon (see Fig. 78-6); it can be used for both anterior and posterior bleeding. Although nasal balloon devices are more expensive than sponges or gauze, they often save the clinician time.

- Place the balloon in a basin of water, inflate it with air according to manufacturer specifications, and observe for air leaks. Then deflate the balloon and coat the tip of the device with petroleum jelly or other lubricant.
- 2. Insert the catheter with the longer portion of the bevel toward the nasal septum to prevent damage to the turbinates or mucosa.
- 3. Inflate the anterior balloon with air according to manufacturer specifications. Do not use saline or tap water. (If the balloon

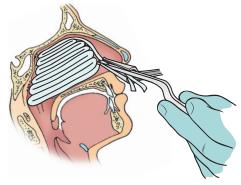

Figure 78-8 Pack folded gauze in layers, from nasal floor to turbinates.

were fluid-filled and it leaked, the patient might aspirate the contents.) If the patient complains of pain at a pressure lower than manufacturer specifications, the balloon may be larger than the nasal cavity. Deflate the balloon until the pain subsides. Do not inflate the posterior balloon at this time unless the patient has such significant bleeding that there is risk of aspiration or exsanguination.

- 4. Observe the patient for further bleeding. If bleeding has stopped, appropriate antibiotic therapy is indicated. These devices are uncomfortable, so analgesics and even sedative medications are generally indicated. If bleeding persists, it is likely due to an area high in the nasal cavity, where the balloon does not reach. One solution is to deflate the balloon, leave it in place, and use anterior petroleum gauze packing on top of it. The balloon can then be reinflated to seal the packing in the upper portion of the anterior nasal cavity. Persistent bleeding may also be due to a bowed septum; packing the contralateral side may halt bleeding by correcting the bowing. If these maneuvers fail to relieve the bleeding, then it is likely the patient has a posterior bleed. At this time, inflate the posterior balloon.
- 5. It is important to document the procedure, notify the follow-up clinician if there is additional packing, and tell the patient that this second packing is present so that it is not left behind when the balloon is removed.

#### **Foley Catheter**

If posterior bleeding is suspected, this technique may be used. It may also be used to provide a posterior buttress for anterior packing. Use a catheter with a 30-mL balloon.

- 1. Prepare the catheter by cutting off the portion of the catheter that is distal to the balloon. Test the balloon by inflating with air and checking for leaks. Deflate the balloon and lubricate the distal catheter with petroleum jelly or equivalent.
- 2. If present, remove the anterior packing.
- 3. Have the patient open his or her mouth widely. Pass the catheter along the floor of the nasal cavity until a small portion of the balloon is visible in the mouth. Inflate the balloon with 7 to 10 mL of air.
- 4. Retract the balloon until it gently lodges against the soft tissue of the choanal arch. If it withdraws into the nasal cavity, advance it back into the nasopharynx and add an additional 3 to 5 mL of air. Keep adding air in 3- to 5-mL aliquots until the balloon lodges upon withdrawal. The balloon is overinflated if the soft palate bulges or the patient complains of pain.
- 5. While an assistant maintains gentle traction on the catheter, place or replace anterior packing with a sponge or gauze as clinically indicated. Place an umbilical clamp on the catheter just outside the nares to secure the device (Fig. 78-9). Pad the umbilical clamp to prevent pressure necrosis.
- 6. Secure the proximal portion of the catheter by taping it to the side of the face. Do not tape it to the neck; if the patient were

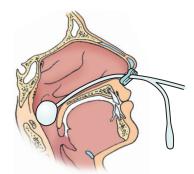

Figure 78-9 Foley catheter as posterior pack.

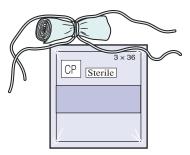

Figure 78-10 Prepare posterior pack.

to turn his or her head, the device might be dislodged. Avoid cutting the proximal catheter—this may cause the balloon to deflate.

7. This procedure can be repeated on the opposite side if necessary. Use antibiotics and analgesics as indicated.

#### **Posterior Packing**

Although posterior packing is described in many textbooks, in practice it is a technically difficult procedure and very time consuming. The author believes it is best left to the otolaryngologist. A simpler technique is to use either a commercially available dual-balloon tamponade device or, failing that, the Foley catheter technique previously described. Balloon tamponade devices are available with channels for the patient to breathe through, making them a more acceptable alternative. A long, expandable sponge may also be attempted, but these are of limited success. Posterior packing is included in this chapter for the sake of completeness or for when the otolaryngologist is not available.

- 1. A posterior pack can be made from a 3 × 36-inch piece of petrolatum gauze rolled into a tight, cylindrical, 3-inch long pack. Two 18-inch pieces of umbilical tape (or heavy nonabsorbable suture) should be tied around the middle of the pack (Fig. 78-10).
- 2. Before inserting the pack, spray the posterior pharynx with anesthetic (e.g., benzocaine spray).
- 3. Next, insert a soft red rubber catheter through the bleeding nostril. Visualize the catheter tip through the patient's open mouth as it passes behind the palate. Pull the tip from the pharynx and out the patient's mouth with forceps. Tie both ends of umbilical tape around the catheter (Fig. 78-11). Pull the catheter back through the nose and snug the roll of gauze against the posterior aspect of the choanal arch (Fig. 78-12). While using something to protect yourself from being bitten (e.g., bite block), guide the pack into this location after pushing it around the soft

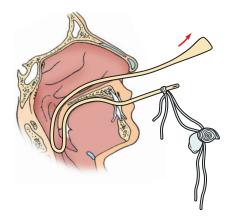

Figure 78-11 Tie or suture posterior pack to catheter.

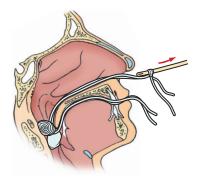

Figure 78-12 Pull pack into position.

palate with your finger. Leave the second piece of umbilical tape hanging from the mouth for pack removal in the future.

**NOTE:** Some clinicians use two soft red rubber catheters to perform posterior packing, inserting one through each nostril and then tying the umbilical tape from each side of the posterior pack to the respective red rubber catheter.

- 4. Secure the posterior pack by tying the piece of umbilical tape that is in the patient's nose around rolled 4 × 4 gauze pads. These rolls should be fitted flush, but not too firmly, against the nares (Fig. 78-13).
- 5. If bleeding slows but does not subside, it will be necessary to place an anterior nasal sponge/tampon or gauze packing.

**NOTE:** Nasal packing fails to stop epistaxis in up to 25% of cases. If bleeding does not subside with these techniques, otolaryngology consult is indicated. Sinus endoscopes can be used to locate the site of bleeding and cauterize it. Septoplasty or ligation of the anterior or posterior ethmoid, internal maxillary, sphenopalatine, or external carotid artery may be necessary. Arterial embolization is another option.

#### Removing Packing

Posterior packing should be removed by a specialist. Anterior packing may be removed in the medical office if the patient is medically stable and healthy, does not take anticoagulant medications, and has not had significant complications of therapy. Have an epistaxis tray in the room in case the nosebleed recurs. *Having good lighting is critical to the procedure*.

- 1. Soften and rehydrate the dressing with saline, taking care not to use so much as to cause the patient to aspirate. Usually, 3 to 5 mL of saline is sufficient. Give the fluid a few minutes to diffuse through the material.
- 2. Follow universal precautions and protect the patient, furniture, and flooring from potential blood spills. Have the patient sit up

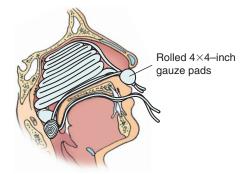

Figure 78-13 Securing posterior pack after placing anterior pack.

- and lean forward, bracing him- or herself with arms grasping a supporting surface—the mattress of the examination table, or the arm of the chair. Instruct the patient to mouth breathe, remain still, and not blow his or her nose or snort.
- 3. With a basin in one hand, and bayonet forceps in the other, gently and smoothly remove the packing.
- 4. Inspect the nasal mucosa for residual bleeding and retained packing. If present, treat appropriately. Often there will be some mild drainage that is nasal mucus mixed with old blood. This drainage rapidly subsides and does not require further treatment.

#### **COMPLICATIONS**

- Hypoxia, causing cardiac or respiratory distress
- Cardiac dysrhythmias
- Pressure necrosis of soft tissue
- Sinusitis
- Nasal septal perforation
- Otitis media
- Toxic shock syndrome
- Aspiration
- Bacteremia
- Allergic reaction to materials or anesthetics

#### **POSTPROCEDURE CARE**

Acetaminophen or narcotics can be used for pain; use of aspirin and other nonsteroidal anti-inflammatories should be minimized because they may encourage bleeding. Patients should be cautioned against nose picking, straining, and bending over. Children's nails should be trimmed short to avoid trauma (parents may want them to wear mittens or socks over their hands at night to protect the nose during sleep). If patients feel that sneezing is imminent, instruct them to keep their mouth open. Patients treated with cautery alone should keep the nasal mucosa moist with petroleum jelly or A&D ointment three times daily for a week. Patients with packing require antibiotics that cover common nasal pathogens such as Stabhylococcus aureus, Strebtococcus bneumoniae, Moraxella catarrhalis, and Haemophilus influenzae. All patients should be instructed to notify health care providers if increasing pain, rebleeding not controlled with 15 minutes of nose pinching/ice application, or fever occurs. Patients should also receive instructions on how to keep the packing moist with a humidifier at home and frequent applications of nasal saline drops. Patients with anterior packing should have the packing removed by an experienced health care provider in 48 to 72 hours. If the patient is medically frail or had significant bleeding, hospital admission may be indicated. Patients needing posterior packing or insertion of a Foley or posterior balloon device generally require admission to an intensive care unit and specialist consultation. Nearly 40% of these patients will eventually require intubation.

#### **PATIENT EDUCATION GUIDES**

### INDIRECT MIRROR LARYNGOSCOPY

Grant C. Fowler • Carlos A. Dumas

Although flexible nasolaryngoscopy is often available for visualization of the upper respiratory tract, indirect mirror laryngoscopy remains the simplest, fastest, least expensive, and often most helpful method of examining the upper tracheal rings, vocal cords, epiglottis, larynx, and hypopharynx. In certain cases, mirror laryngoscopy combined with an adequate history will be all that is needed to make the diagnosis. Experienced clinicians appreciate the glare-free lighting of the laryngeal structures provided by mirror laryngoscopy, which allows for observation of subtle color variations. Mirror laryngoscopy requires very little preparation, very little time to perform, and very little effort to care for only a few inexpensive instruments. The upper respiratory tract in most adults and children older than 6 or 7 years of age will be easily visualized by experienced clinicians. Examples of when mirror laryngoscopy may be useful include when nasolaryngoscopy is not available, in patients at low risk of malignancy, and during follow-up for a known lesion after complete nasolaryngoscopy has excluded other lesions. It may also be useful as a preliminary examination before nasolaryngoscopy. To keep oriented, clinicians should recall that when using a mirror, everything is seen in reverse. Before performing the procedure, it may be helpful for clinicians to refamiliarize themselves with the anatomy of the oropharynx, hypopharynx, and larynx (see Figs. 77-4 through 77-6 in Chapter 77, Nasolaryngoscopy).

NOTE: When not done on a regular basis, the necessary coordination of patient and instruments to perform mirror laryngoscopy may make it difficult, and occasionally impossible, to examine the patient's larynx—even for expert laryngologists. This fact was highlighted when a survey in the 1980s found that less than 30% of primary care clinicians practicing in Ohio were able to visualize a larynx, and that less than 4% included inspection of the larynx as part of their complete physical examination. Primary care clinicians in Ohio are probably representative of those elsewhere, and a few commented anonymously that they had never visualized a larynx!

#### **INDICATIONS**

- Chronic hoarseness (>3 weeks)
- Suspected or previous neoplasm
- Chronic cough
- Chronic dyspnea
- Halitosis
- Head or neck mass or adenopathy suggestive of malignancy
- Dysphagia
- Phonation disturbance such as vocal weakness in the elderly or psychogenic dysphonia
- Chronic foreign body sensation in pharynx
- Hemoptysis
- Suspected laryngeal foreign body
- Acute onset of hoarseness after straining voice
- Stridor, particularly inspiratory stridor
- Post-traumatic evaluation
- Any chronic unilateral upper respiratory complaint in a smoker

 Any clinical situation in which visualization of the oropharynx, hypopharynx, and larynx will aid in diagnosis or therapy

#### **CONTRAINDICATIONS**

- Acute epiglottitis. (Patient usually has a toxic appearance, will be leaning forward, drooling secretions, and may not be able to talk.) Laryngoscopy may precipitate complete airway obstruction.
- Infants and young children who are unable to cooperate.
- Acute inflammation or infection of the throat (relative contraindication).
- Patient who cannot open his or her mouth adequately (relative contraindication).

#### **EQUIPMENT**

- Bright headlight or head mirror with external light source
- No. 4 and no. 5 laryngeal mirrors; smaller sizes for children
- 4 × 4 inch gauze sponges
- Local anesthetic: lidocaine\* spray (2% to 4%) or benzocaine\* spray (14%)
- Goggles, gloves, and mask (to follow universal blood and body fluid precautions)
- Alcohol lamp or bowl of hot water to warm mirrors (optional)

### PREPROCEDURE PATIENT PREPARATION AND EVALUATION

After obtaining and performing a thorough head and neck history and examination, as well as the remainder of a complete history and physical examination, explain the indications and alternatives for the procedure as well as what will happen during the procedure. Every effort should be made to relax the patient. The clinician should maintain a gentle, unhurried manner, and perhaps show the patient the instruments by touching the patient with the instruments in a nonthreatening area such as the hand or arm. Gently inform the patient that it will be important to try to relax and that the mirror will be placed in the top of the back of his or her mouth, avoiding the throat and the gag reflex. The patient should know that if the procedure is performed properly and an anesthetic is used, the risk of gagging should be minimized, especially if the patient keeps his or her eyes open and looks straight ahead (which diminishes the gag reflex). Possible complications should be explained, and the patient should remove any dentures.

#### **TECHNIQUE**

1. The patient should sit upright and straight, preferably in a high-backed chair with a headrest. Tell the patient to lean slightly forward. The head and jaw should be jutted forward in a "sniffing" position (Fig. 79-1). The chin should be up.

<sup>\*</sup>Should be used with caution in those who have a history of an allergy or sensitivity to the agents (see Chapter 4, Local Anesthesia).

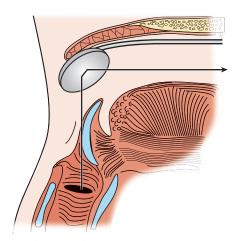

**Figure 79-1** Proper positioning of the patient is essential for successful visualization of the larynx.

- 2. Sit slightly to the side of the patient. Sitting slightly higher than the patient will also facilitate visualization of the laryngeal structures. Position the light source so that the light is directed parallel to your visual axis and focused on the patient's posterior pharynx. The examiner should be comfortable and understand that the use of a hurried approach can make this procedure more difficult. The clinician should follow universal blood and body fluid precautions.
- 3. Spray the patient's pharynx with the anesthetic and have him or her gargle and spit it out.
- 4. Select the largest mirror that will fit comfortably into the back of the throat, and warm it over the alcohol lamp, in the warm water, or inside the patient's cheek. Warming the mirror should prevent fogging. If the mirror is externally warmed, check its temperature on the back of your hand to make sure that it is not too hot before inserting. In addition, you can touch the warmed mirror to the hand or arm of the patient, not only to reassure the patient that the temperature is acceptable, but to demonstrate that the mirror is nonthreatening.
- 5. Have the patient protrude his or her tongue. Cover it with gauze and grasp it firmly between the thumb and middle finger of your nondominant hand. In effect, the ventral surface of the tip of the tongue is rolled over your middle finger. Do not pull so hard as to cause discomfort. Use your index finger to retract the patient's upper lip.
- 6. Ask the patient to breathe in and out through the mouth or to "pant like a puppy." This opens the space between the soft palate and the tongue. Remind the patient to keep his or her eyes open, and to perhaps focus on your forehead or headband to serve as a distraction.
- 7. With the warm mirror in your dominant hand and the glass surface pointing downward, slowly introduce the mirror and visualize the epiglottis. Next, slowly and gently apply the posterior aspect of the mirror to the uvula and a portion of the soft palate. With a smooth, gentle movement, slowly lift them upward and backward out of the way. Avoid touching either the posterior pharyngeal wall or the base of the tongue. Touching these might stimulate the gag reflex (Fig. 79-2).

**NOTE:** In certain patients, adequate anesthesia is not attainable for this portion of the procedure. In those cases, flexible nasolaryngoscopy should be performed.

8. With the mirror gently lifting the uvula and soft palate out of the way, tilt it in various directions to visualize the larynx, the hypopharynx, and the anterior oropharynx, including the base of the tongue. Move your head toward and away from the mirror

**Figure 79-2** Laryngeal mirror is inserted into the pharynx, lifting the uvula but avoiding contact with the posterior pharyngeal wall.

- to focus the light source maximally on visualized objects (Fig. 79-3). Continue to encourage the patient to breathe gently in and out through the mouth. If the structures are not adequately visualized after lifting the soft palate and uvula out of the way, check the positioning of the patient's chin and neck. Reposition if necessary.
- 9. With the larynx visualized (see Fig. 77-6 in Chapter 77, Nasolaryngoscopy), observe vocal cord activity during quiet respiration. Next, observe cord activity while the patient holds a prolonged high "eee" sound. This lengthens the vocal cords and moves the larynx upward vertically, which should allow visualization of the anterior commissure. Observe for symmetry of cord mobility and for edema, hemorrhage, erythema, nodules, or a mass on the cords or in the surrounding structures. Note any other mucosal or structural abnormalities.

NOTE: All structures viewed will be seen in mirror image (upside-down and backward).

10. If the mirror fogs during the procedure, it needs to be reheated. If externally heated, it needs to be tested again on your hand or arm before use. For those patients whose pharynx is not suitably visualized by this technique, or for those in whom a closer evaluation of an abnormality is indicated, nasolaryngoscopy should be performed or referral to an otolaryngologist considered.

**Figure 79-3** The tongue is pulled forward with gauze, and the mirror is tilted in various directions to visualize the larynx, hypopharynx, and anterior oropharynx.

#### **FINDINGS**

- Epiglottis: Usually has a slightly curved and regular upper edge
  but is sometimes acutely curved and conical ("infantile type").
  It may hang backward and obscure the view of the cords in the
  relaxed state or hang forward to hide the valleculae. If the epiglottis is floppy, small lesions on the laryngeal surface of the epiglottis may be difficult to see. The apices of the pyriform sinuses are
  also not usually visualized. The epiglottis rises upward and forward
  during phonation.
- Aryepiglottic folds: May have swelling or ulceration.
- Interarytenoid area: May be thickened or covered with papilla.
- False cords: May show swelling or ulceration.
- Vocal cords must be examined for the following:
  - Color: Normal color is pearly white.
  - Movement: May be restricted by paresis or by infiltration of tumor. Arthritis of cricoarytenoid joint may also cause limited movement.
  - Surface: May be intact or ulcerated.
  - Edge: May be irregular.
  - Anterior commissure: Not always seen because of anatomic variations.
- Subglottic space: Difficult to examine, but swellings may be seen below the level of the vocal cords.

#### **COMPLICATIONS**

- Possible laceration of the undersurface of the tongue from stretching the tongue over the teeth
- Possible adverse reaction to anesthetic
- Vomiting, with possible aspiration
- Failure to diagnose an abnormality because of inadequate visualization

#### **CPT/BILLING CODE**

No separate code is available for this procedure. Consider using a more comprehensive E/M code.

#### **ICD-9-CM DIAGNOSTIC CODES**

- 161.9 Laryngeal cancer, NEC
- 305.1 Nicotine addiction, or addiction in remission
- 306.1 Psychogenic dysphonia
- 784.2 Neck mass
- 784.41 Aphonia
- 784.49 Hoarseness
- 784.99 Halitosis
- 786.05 Dyspnea, chronic
- 786.1 Stridor
- 786.2 Cough, chronic
- 786.3 Hemoptysis
- 787.2 Dysphagia
- 933.0 Foreign body in hypopharynx, nasopharynx, oropharynx, or pharynx
- 933.1 Foreign body, larynx

### PERITONSILLAR ABSCESS DRAINAGE

Roger K. Waage

Peritonsillar abscess, an infection in the space between the palatine tonsil and the pharyngeal constrictors, is the most common deep infection or abscess of the head and neck. Approximately 45,000 cases of peritonsillar abscess occur annually in the United States, usually in patients in the second or third decade of life; it rarely occurs in immunocompetent children younger than 6 years of age. Symptoms include fever, malaise, severe sore throat, trismus, odynophagia, and dysphagia with drooling. The patient may be dehydrated from a lack of oral intake. Pain is often referred to the ear, and the patient may have a voice with muffled resonance known as a "hot potato" voice. Signs of peritonsillar abscess include nonexudative pharyngitis in the majority of cases, marked edema of the soft palate, and a fluctuant fullness of the tonsil, which is covered superiorly by a shiny membrane. The classic sign is deflection of the swollen uvula to the opposite side (Fig. 80-1). There is often inferior and medial displacement of the affected tonsil. Tender cervical adenopathy is usually present.

The local anatomy must be understood before attempting to aspirate or drain a peritonsillar abscess. The palatine tonsils lie between the palatoglossal and palatopharyngeal arches. These two pillars form the anterior and posterior borders of the tonsil. The surface of each tonsil has a covering of mucosa with an irregular number of indentations known as tonsillar crypts. Beneath the mucosa, each tonsil is surrounded by a fibrous capsule. A peritonsillar abscess is a collection of pus between the fibrous capsule of the tonsil and the superior constrictor muscle of the pharynx, which forms the lateral wall of the tonsil. Progression of pus formation and lateral extension of cellulitis irritate the surrounding musculature, particularly the internal pterygoids, resulting in spasm and trismus. It is also important to note for this procedure that the internal carotid artery lies approximately 2.5 cm posterolateral to the tonsil and that the facial artery lies lateral to the tonsil.

Historically, it was thought that a peritonsillar abscess developed as a progression of an acute exudative tonsillitis. Currently, a peritonsillar abscess is thought to originate in Weber's salivary glands, which are found in a space just above the tonsil known as the *supratonsillar fossa*. Weber's salivary glands are a group of about 20 mucous salivary glands that assist with digestion of food particles trapped in the tonsillar crypts. They are connected to the palatine tonsil by a duct that extends to the surface of the tonsil. Supporting the theory that Weber's glands are involved in the pathogenesis of peritonsillar abscess are the facts that a peritonsillar abscess can occur after tonsillectomy, even while the patient is on appropriate antibiotics, and the majority of abscesses are found in the superior pole of the palatine tonsil. Only 20% of abscesses are found in the mid-tonsil, and only 10% occupy the lower pole.

A peritonsillar abscess is usually polymicrobial. The most common aerobic organisms are *Streptococcus pyogenes* (group A beta-hemolytic *Streptococcus*) and *Staphylococcus aureus*. The most common anaerobes are *Bacteroides* and *Fusobacterium*. Throat cultures are of no benefit, and cultures from the aspirate have rarely been found to be helpful for selection of antibiotics.

The differential diagnosis of peritonsillar abscess includes unilateral tonsillitis, peritonsillar cellulitis, neoplasm, retropharyngeal abscess, leukemia, herpes simplex tonsillitis, infectious mononucleosis, foreign body aspiration, aneurysm of the internal carotid artery, and retromolar abscess. The most common entity that is confused with peritonsillar abscess is peritonsillar cellulitis. Peritonsillar cellulitis has the same symptoms, and perhaps similar physical findings, but because there is no pus between the tonsil and the lateral muscles, there is no fluctuance in the peritonsillar area. Ultrasonography may help distinguish between cellulitis and abscess, noninvasively. However, intraoral ultrasonography requires a skilled and experienced sonographer and the examination may be limited by trismus. Intraoral ultrasonography is probably most useful for locating the abscess when aspiration or incision and drainage is unsuccessful. Transcutaneous ultrasonography can also be performed by placing the transducer over the submandibular gland and scanning the tonsillar area, but there is a loss in the resolution of the image because of the distance from the transducer, so this is rarely used. Computed tomography (CT) is occasionally helpful. The CT should be done with contrast and may be helpful for ruling out an extension of the abscess.

The initial treatment of all patients with peritonsillar abscess should include adequate pain relief, hydration, and antibiotics. There is no consensus on choice of antibiotics. Penicillin, clindamycin, or cephalosporins are all reasonable as a first choice. Use of oral penicillin in doses of 500 mg four times daily has resulted in reasonable cure rates. Some clinicians add metronidazole if the clinical response in 24 hours is less than expected. Other clinicians advocate combining steroids with antibiotics. A recent study of rural field hospitals in the Indian Health Service suggested that high-dose steroids combined with cephalosporins, intravenous hydration, and analgesia were effective in reducing the number of patients needing to be air-evacuated from remote locations (see Lamkin and Portt, 2006).

Historically, the surgical treatment of peritonsillar abscess has been either abscess tonsillectomy or incision and drainage. If untreated, the abscess can rupture, possibly resulting in laryngeal aspiration, pneumonia, sepsis, or death. An untreated abscess can also spread locally or hematogenously, causing extensive local infection or even meningitis. Patients with a peritonsillar abscess and a history of three episodes of tonsillitis in the past year should probably be sent for an abscess tonsillectomy. However, for those patients without recurrent tonsillitis, there is growing evidence that needle aspiration is the treatment of choice. Needle aspiration has been shown to have an 85% to 100% success rate. Of those patients who respond initially, only 10% will have a recurrence. A second needle aspiration should also have a high success rate. Patients who fail a second or third needle aspiration should probably have an abscess tonsillectomy. (Even those patients who respond to a third aspiration should probably have a tonsillectomy, especially if this is the third infection in a year; see Chapter 83, Tonsillectomy and Adenoidectomy). The small percentage of patients whose abscess fails to resolve with a needle aspiration should probably have an

**Figure 80-1** Peritonsillar abscess on patient's right side. Note fluctuance, lack of exudate on tonsil, soft palate edema, and deviation of uvula to the opposite side.

incision and drainage procedure or be referred to an otolaryngologist to rule out a possible pterygomaxillary space abscess. An algorithm for the management of peritonsillar abscess is shown in Figure 80-2. Considering that the incision and drainage technique is now typically reserved for more difficult cases, it is not surprising that the recurrence rate is slightly higher than in the past, ranging from 6% to 24%.

Needle aspiration does have some drawbacks. It is painful, invasive, and performed somewhat blindly. A series of 12 patients evaluated by Haeggstrom and associates demonstrated that abscesses

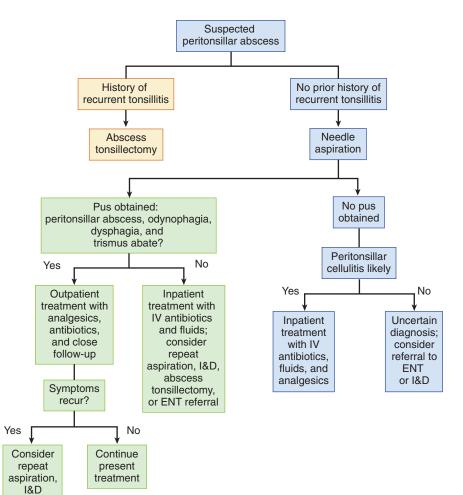

were located within 4 to 25 mm from the carotid artery. In addition, needle aspiration samples only one area in the tonsillar fossa and may require repeated attempts. From 12% to 24% of abscesses are missed on the first aspiration attempt. However, it is relatively simple to perform, even by those with little experience and who are not ear, nose, and throat specialists, and it does not require expensive or specialized equipment. A study performed in 1980 (Herzon and Aldridge) on the efficacy of needle aspiration showed that 80% of aspirations were performed by interns and 20% by emergency medicine specialists. Successful aspiration or incision and drainage may also help the patient avoid a hospitalization.

#### **INDICATIONS**

Peritonsillar abscess in a patient who is not indicated for abscess tonsillectomy

### CONTRAINDICATIONS (ABSOLUTE AND RELATIVE)

- Septic shock or impending respiratory compromise (patient should first be stabilized)
- Uncooperative patient
- Operator unfamiliar with anatomy
- Anticoagulated patient or patient with coagulopathy (either the anticoagulation/coagulopathy should be reversed or otolaryngology consulted)
- Inadequate equipment

**Figure 80-2** Algorithm for management of peritonsillar abscess. ENT, ear, nose, and throat; I&D, incision and drainage.

#### **EQUIPMENT**

#### **Needle Aspiration**

- Topical anesthetic—lidocaine, tetracaine, or benzocaine (Cetacaine) spray or 4% cocaine
- 2% lidocaine with epinephrine 1:100,000 in a 3- to 5-mL syringe with a 25- or 27-gauge, 1.5-inch needle or tonsil needle
- 18-gauge 1.5-inch or longer needle or spinal needle
- 10-mL syringe

**NOTE:** As a guide to keep from going too deep, place a piece of tape or Steri-Strip 8 mm proximal to the needle tip or cut 8 mm off the end of the needle cover and put it back on the needle, leaving 8 mm of needle exposed.

- Suction: tonsillar or no. 8 Frazier
- Good lighting: headlight or head mirror with gooseneck lamp
- Kidney basin
- Tongue depressor
- Bite block or heaped gauze (as thick as the clinician's finger) folded over the patient's incisor teeth to help the clinician avoid being bitten when palpating the area
- Surgical assistant to help with the equipment and procedure
- Gloves and mask for the clinician to observe universal blood and body fluid precautions

#### **Incision and Drainage**

All of the aforementioned, plus a curved Kelly or tonsillar clamp and a no. 15 scalpel blade marked with tape or Steri-Strip 8 mm from the tip

#### PREPROCEDURE PATIENT EDUCATION

The procedure of choice for most patients is needle aspiration, so this procedure should be explained, as well as the risks and any alternatives. Advise the patient that he or she may experience some discomfort while attempting to hold the mouth (or as it is held) open and when the local anesthetic is injected (even though the pharynx will be sprayed first with a topical anesthetic). The patient may also experience some discomfort when the abscess is aspirated or incised and drained. If aspiration fails, the procedure may shift to incision and drainage, and the patient should know the difference. He or she may gag or experience fluid running down the throat. Fortunately, the pus can usually be aspirated or incised and drained successfully, and, if so, the symptoms will improve dramatically. If this is successful, the patient can be treated with oral antibiotics and analgesics, and hospitalization can be avoided. If the abscess is not successfully drained or if the symptoms do not resolve, further treatment and hospitalization may be required. The patient should also be told that there is a 10% chance of recurrence after aspiration and a 6% to 24% chance of recurrence after incision and drainage. If the abscess recurs after successful aspiration, there is a high success rate for merely repeating the aspiration. However, even if aspiration is successful three times, the patient would probably benefit from tonsillectomy, especially if three infections have occurred in the same year. Fortunately, there are new methods available for tonsillectomy and adenoidectomy (see Chapter 83, Tonsillectomy and Adenoidectomy) that can usually be performed in the outpatient setting and that minimize postoperative pain and recovery time. Obtain a signed informed consent from the patient or his or her representative for all of these procedures.

#### **TECHNIQUE**

#### **Precautions**

One disaster to avoid is aspiration or incision of the carotid or facial arteries or an undiagnosed carotid artery aneurysm. (Fortunately,

there are no recent reports in the literature of this occurring, so it is extremely rare.) Another disaster to avoid is patient aspiration of purulent material into his or her lungs. The risk of the first can be minimized by directing the needle or scalpel only posteriorly when performing the procedure (the major vessels are located laterally) and never inserting it more than 8 mm. The risk of the latter can be minimized by ensuring adequate wall operative suction at the time of incision and drainage.

#### **Procedure**

- 1. Seat the patient leaning slightly forward, in the sniffing position, at eye level with the operator. His or her neck should be supported posteriorly to prevent the patient from moving abruptly. A kidney basin should be available for the patient to expectorate. Suction must be readily available with either a tonsillar or no. 8 Frazier tip. Good lighting is necessary, provided by either a headlight or a head mirror with a bright light source behind the patient.
- 2. Have the patient open his or her mouth as wide as possible. If trismus restricts jaw motion, the patient may need some encouragement to open more widely. Mild pressure on the lower jaw may also be necessary to help open the mouth. The cheek may be retracted laterally to improve visualization. Your assistant can help provide exposure by placing mild pressure on the jaw and lateral traction on the cheek. For moderate to severe trismus, sedation may be beneficial (see Chapter 2, Procedural Sedation and Analgesia). Palpate the soft palate and tonsil to localize the fluctuant area, and administer topical anesthetic to the affected side. A bite block or some heaped gauze folded over the patient's incisor teeth may help the clinician avoid being bitten. Be prepared to avoid a bite when palpating the area because the patient may not be able to hold his or her mouth open for very long. The patient may also gag when the area is palpated. When the topical anesthetic has taken effect, inject 2% lidocaine with epinephrine (using a 25- to 27-gauge, 1.5-inch needle, or tonsil needle) into the mucosa, just above and lateral to the tonsil. Avoid injecting into the abscess.
- 3. After a few minutes, attempt aspiration. Hold the tongue depressor in your nondominant hand and the aspirating syringe in your dominant hand. You may need to ask your assistant to create suction with the syringe. Insert the 18-gauge long or spinal needle on a 10-mL syringe, and direct it straight posteriorly. When inserted, attempt aspiration (Fig. 80-3). The needle should not be inserted more than 8 mm. If you aspirate pus, continue until no more pus returns. Scientific evidence suggests there is no reason to culture the aspirated fluid, which is usually between 2 and 14 mL of pus.
- 4. If you do not aspirate any pus, withdraw the needle slightly and redirect inferiorly. When performing this procedure, be aware that the carotid artery lies approximately 2.5 cm posterior and lateral to the tonsillar pillars. In addition, the more the needle is directed toward the lower pole of the tonsil, the more likely it is to enter the carotid artery. Therefore, make sure it is only directed posteriorly. Never aspirate lateral to the molar. If blood returns on aspiration, the procedure should be stopped, the needle should be removed, and direct pressure should be applied to the puncture site. An otolaryngologist should be consulted immediately.
- 5. If the aspiration is unsuccessful and the diagnosis of peritonsillar abscess is certain, immediate incision and drainage can be performed. With a no. 15 scalpel blade directed posteriorly, make an incision just through the mucosa in the upper pole of the tonsil at the point of maximum fluctuance (prominence; Fig. 80-4). Maximum fluctuance (prominence) is usually demonstrated as a shiny membrane over the abscess. Avoid inserting the scalpel blade more than 8 mm. After an incision is made through this membrane, there is often prompt expression of pus. Immediate and aggressive suction is required. Having the surgical assistant ready

Figure 80-3 Aspiration of peritonsillar abscess. **A,** Abscess. **B,** The abscess should be anesthetized topically, injected with 2% lidocaine with epinephrine, and then aspirated with an 18-gauge long needle or spinal needle at the point of maximal fluctuance (prominence).

with the suction placed at the incision site, before the incision is made, often reassures the patient and keeps him or her comfortable. It may also help the patient avoid any gagging or drowning sensation that can occur when pus is released into the pharynx.

**NOTE:** When surveyed, the initial procedure performed by most otolaryngologists for a peritonsillar abscess is incision and drainage, whereas the initial procedure by most nonotolaryngologists is aspiration.

- 6. Sometimes the incision needs to be widened with a curved Kelly or tonsillar clamp. Any loculations that are apparent should be opened. Loculations are especially common inferiorly. Any remaining pus or blood should be suctioned before the procedure is finished. The patient can then rinse his or her mouth with tap water, normal saline, or peroxide. The patient should be observed directly for a few minutes after incision and drainage for any persistent drainage. If drainage persists, the patient should be admitted for intravenous antibiotics. The patient should also be observed for at least an hour before discharge to ensure stable vital signs and absence of bleeding.
- 7. All patients successfully treated by needle aspiration or incision and drainage may be sent home with penicillin (or erythromycin if they are allergic to penicillin). Liquid elixirs are much easier for the patient to swallow. Anaerobic coverage with metronidazole or clindamycin is probably not necessary.

#### **COMPLICATIONS**

- Hemorrhage
- Tracheal aspiration of purulent material

- Respiratory distress
- Pneumonia
- Failed aspiration or incision and drainage, persistent cellulitis
- Recurrence

#### SAMPLE OPERATIVE REPORTS

See sample operative reports online at www.expertconsult.com.

#### POSTPROCEDURE PATIENT EDUCATION

All patients who have been treated for a peritonsillar abscess need adequate antibiotics and analgesia, preferably in the liquid form. Warm gargles may help keep the area clean and provide mild analgesia. The patient will want to maintain a liquid or soft diet until the discomfort has resolved. Patients should be instructed to return if they experience a recurrence of symptoms, fever greater than 101° F, severe pain, significant bleeding, or trouble breathing or swallowing. A follow-up appointment within 48 hours should be scheduled.

## Management of Dental Injuries and Reimplantation of an Avulsed Tooth

Grant C. Fowler

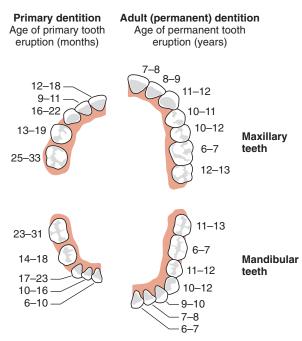

Dental trauma, ranging from a slight chip of the enamel to avulsion of a tooth, causes some of the most common injuries to the face. An occlusive misadventure (e.g., biting a hard object or a seizure) or a blow to the face can cause dental trauma. Up to 10% of emergency department visits are due to dental trauma. Injuries to the maxillary central incisors account for 70% of dental injuries, subluxations account for about 50% of injuries to the teeth, and up to 5 million avulsions occur annually in the United States. It is estimated that 50% of children will experience dental trauma. Management depends on the age of the patient and the nature of the injury. Often, the primary care clinician is the first to evaluate such an injury. Occasionally, the clinician will receive a phone call from a patient requesting guidance after a fracture, subluxation, luxation, or avulsion has occurred. Proper management of dental trauma may minimize pain and disfigurement. For example, knowledge of proper storage and treatment of an avulsed tooth is crucial to optimize the chances of successful reimplantation.

**NOTE:** If a tooth or portion of a tooth is missing and it cannot be unequivocally located by history or physical examination, attempts should be made to locate it with radiographs. Facial films may find it in a maxillary sinus (which may necessitate surgery), a chest radiograph may document that it has been aspirated (requiring bronchoscopic retrieval), or abdominal films may document that it has been swallowed. Also, with a luxation or avulsion, care should be taken to determine whether a tooth is primary (i.e., deciduous, milk, temporary) or permanent in children because it may change the management (Fig. 81-1). This determination may be tricky in children between the ages of 6 and 12 years who may have "mixed" dentition. In addition, patients (parents) should be aware that it may not always be possible to detect the presence or extent of a dental fracture with the initial examination and radiographs. Root fractures (although rare), which may require extensive dental care, are notorious for avoiding detection by radiography; they may be diagnosed only later by radiography, as they are healing.

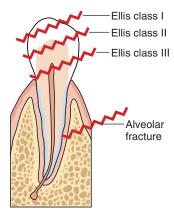

Management of a dental fracture is based on the extent of the fracture (Fig. 81-2) and the age of the patient. Ellis I fractures involve only the enamel of the tooth. They may be a mere "chip" off of the tooth. Management is necessary only if a resultant sharp edge is disturbing the adjacent soft tissues. In that case, a nail file (emery board) can be used to file down the edge. Referral can be made to a general dentist for cosmetic restoration. Patients or parents may appreciate being reassured that the tooth can usually be restored to its natural appearance with the use of enamel-bonding plastic materials.

Ellis II fractures, which account for 70% of tooth fractures, not only involve the enamel but also expose the dentin layer, which has

a creamy- or ivory-yellow color compared with the white enamel. Beneath the dentin lies the pulp, which continually lays down dentin for the life of the tooth, and the goal of emergency management is to maintain the vitality of this pulp. Patients usually complain of sensitivity to hot, cold, or even air passing over the exposed surface when breathing. They should be warned that any trauma to a tooth may lead to pulpal necrosis or tooth resorption, regardless of management, and that dental referral is required within 24 hours. Patients younger than 12 years of age have less dentin, so there is usually less discomfort. However, because dentin is a microtubular structure that can allow bacteria to penetrate the pulp, tooth fractures in children and adolescents involving the dentin are more serious because the pulp is more likely to be contaminated. Fortunately, this age group also has much greater pulpal regenerative ability. Early treatment may prevent contamination of the pulp and

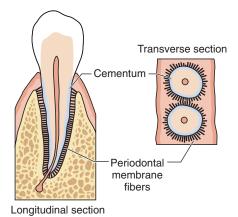

**Figure 81-1** The normal eruptive patterns of primary and permanent teeth. Extra or fewer teeth are common in both types of teeth. (Redrawn from Upadhye S, Ross DJ: Fractures tooth management. In Reichman EF, Simon RR [eds]: Emergency Medicine Procedures. New York, McGraw-Hill, 2004, pp 1397–1402.)

**Figure 81-2** Ellis classification for fractures of anterior teeth. (From James DM: Immediate management of tooth fracture and avulsion. In James DM [ed]: Field Guide to Urgent and Ambulatory Care Procedures. Philadelphia, Lippincott Williams & Wilkins, 2001, pp 36–39.)

the need for subsequent root canal, so a pediatric or general dentist should be notified right away. For patients older than 12 years of age, because they have more dentin and less pulp, referral can be made for the next working day. Regardless of age, warming the sterile saline before flushing may decrease temperature sensitivity. A thin layer of a protective dressing that is also a sedative to the pulp (e.g., calcium hydroxide paste or zinc oxide with eugenol; see Suppliers section), or even toothpaste, should be applied with a small applicator. The exposed dentin should be covered and then the paste covered with a dry gauze. To maintain a dry field while working, cotton gauze or rolls can be placed on either side of the tooth. Patients older than 12 years of age should then be advised to avoid extremes of intraoral temperatures. A piece of dental foil or aluminum foil placed over the paste-covering gauze may provide additional protection from discomfort associated with temperature extremes until the dentist can see the patient. If available, instead of gauze, three to four coats of dental varnish (see Suppliers section) or clear nail polish can be painted over the paste. Allow time to dry between coats; this may help protect against temperature extremes.

Ellis III fractures expose the pulp of the tooth. Again, because there is more pulp relative to dentin in children, fractures involving the pulp are more common in children. Pulp can easily be distinguished from dentin because exposed pulp produces a red blush or a drop of blood when brushed with sterile gauze. These fractures are a dental emergency, and the usual treatment is removal of the pulp (pulpotomy). Significant delay in care can lead to long-term pain

**Figure 81-3** Arrangement of periodontal fibers. The cementum is a thin cell layer lining the root between the root and the periodontal fibers. Together, the cementum, periodontal fibers, and alveolar bone form the attachment apparatus.

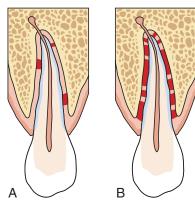

Figure 81-4 Slightly (A) and moderately (B) concussed tooth.

and abscess formation. The clinician should not attempt to probe the pulp or remove any material; instead, the affected area should be covered with aluminum foil, adequate analgesia should be provided, and oral antibiotics effective for mouth flora should be prescribed. Such a fracture can cause considerable pain, so a dental anesthetic nerve block may be appreciated. The patient should then consult a dentist immediately because definitive treatment for all but the smallest pulpal exposures is endodontic or root canal therapy. If a dentist will not be available, bleeding can be stopped by dripping dilute epinephrine (or lidocaine with epinephrine) over the site. Injection of lidocaine with epinephrine around the tooth also often provides hemostasis. If unsuccessful, pressure can be applied with a saline-moistened, sterile cotton-tipped applicator. It may take 3 to 5 minutes for hemostasis. A thick coat of calcium hydroxide or zinc oxide with eugenol paste can then be applied to the tooth and an adjacent tooth (for stability), making sure that it is not so thick as to interfere with occlusion. If a dentist is not available, a minimal Ellis III fracture (<1 to 2 mm pulp exposure) can be treated as an Ellis II fracture and followed up by a dentist in 24 hours, although this alternative is less than ideal.

Teeth are held in place by surrounding periodontal membrane fibers and ligaments, a fragile cell layer lining the root known as the cementum, and alveolar bone (Fig. 81-3). These structures combined are known as the attachment apparatus. The crown is the hard enamel portion of the tooth located above the gum line. With trauma, periodontal fibers and the attachment apparatus may be concussed (Fig. 81-4), a tooth may be subluxed (ligaments damaged) or luxated (dislocated) extrusively, intrusively, or laterally, or an entire tooth may be avulsed (Fig. 81-5). Concussion is defined as injury to the tooth, and although the tooth will be tender to palpation, there will be no increased mobility. The radiograph will be negative. If examination of the surrounding gingiva reveals blood, there has also usually been ligamentous damage, which is confirmed if the tooth can be wiggled. Ligamentous damage can be caused by subluxation or luxation, with subluxation resulting in a loose tooth that may or may not be sensitive to touch. Extrusive luxation results in a misaligned, loose tooth that is often elevated above those bordering it.

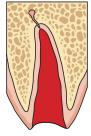

Figure 81-5 Avulsed tooth.

The patient frequently complains of malocclusion because this tooth contacts the opposing teeth early when chewing. Intrusive luxation is a more severe form of luxation in which the tooth is driven into the alveolar bone. With primary teeth, this process can cause damage to the permanent tooth bud. Depending on the force involved, the tooth can even be driven into the maxillary sinus and appear avulsed. If intrusive luxation is suspected and the tooth is not visible, a radiograph may be needed to locate the tooth. Although an extrusive luxation is the result of a partial avulsion or dislodgment of the tooth, there is no fracture, so the radiograph will be negative. Lateral luxation is the result of an alveolar bone fracture with lateral displacement of the tooth in the mesial, distal, buccal, or lingual direction. A radiograph should confirm the fracture.

Treatment of a concussed tooth is directed by the severity of the discomfort. Nonsteroidal anti-inflammatory drugs (NSAIDs) and a soft diet may be all that is necessary to manage the pain. For subluxation, a minimally mobile tooth will usually "firm up" over a week or two, and splinting usually is not required. Severely subluxed primary teeth should be extracted; otherwise, concussed and subluxed primary teeth are treated in the same manner as permanent teeth. For subluxed teeth, the patient should maintain a soft diet and avoid undue pressure on the affected tooth during that time, and may benefit from NSAIDs for pain control. For either concussion or subluxation, referral to a dentist may be prudent, not only to confirm the diagnosis, but also to exclude more serious injury.

An extrusively luxated primary tooth should be removed; conversely, and extrusively luxated permanent tooth needs to be repositioned. Firm, gentle pressure will usually realign the tooth to its original position, and this maneuver may be better tolerated if a local anesthetic is injected. Avoid excessive pressure when attempting this maneuver; a hematoma may be blocking repositioning and require more definitive care by a dentist. If repositioning is successful, splinting should be provided to stabilize the tooth for 1 to 2 weeks during healing, either by a dentist with flexible wire splinting or by a primary care clinician using a cold-curing periodontal pack (see Suppliers section) or dressing until a dentist, oral surgeon, or maxillofacial surgeon can provide definitive care (ideally within 24 hours). To use a cold-curing periodontal pack, thoroughly mix equal portions of the epoxy and catalyst on an uncontaminated surface until it has the consistency of putty. It should be allowed to dry slightly for a few minutes and then applied by molding it to the exterior, buccal surface of the tooth and adjacent teeth on either side. Avoid covering any of the occlusal surface. The patient should remain in the clinic until the splinting material has completely hardened; reexamination ensures the absence of impingement of an occlusal surface or soft tissue sufficient to cause local irritation. Dental utility wax or beeswax may be used in the same fashion if a cold-curing periodontal pack is not available.

Intrusive luxation is a more serious injury, resulting in alveolar fracture. Management consists of defining the extent of injury (e.g., is a sinus involved?), locating the tooth, providing analgesics, and referral. Laterally luxated primary teeth should be extracted. With permanent teeth, because lateral luxation causes a fracture, respositioning the tooth may be more difficult. However, by grasping the tooth firmly between thumb and forefinger, the clinician will usually be able to realign the tooth. After referral, stabilizing with a splint is necessary for a minimum of 2 weeks.

In the event of avulsion, the neurovascular supply is disrupted. Although primary teeth are usually not reimplanted (to avoid damaging the developing permanent teeth), the more rapidly a permanent tooth is reimplanted, the more likely the tooth will remain viable. If the tooth can be replanted within 5 minutes, there is a greater than 80% chance that the tooth will remain vital. Given this urgency, bystanders or clinicians should not be overly concerned about cleaning or flushing the socket or tooth before reimplanting. When preparing for reimplantation, only the crown should be touched; touching the root can devitalize it. Significant debris and large clots can merely be brushed off; small clots or dirt can be

removed by the patient by placing the tooth under his or her tongue for a few seconds. If it is going to be reimplanted immediately, the tooth can be flushed with saline or tap water. Reimplantation should then be performed with follow-up by a dentist.

For the tooth that is not immediately reimplanted, proper storage is crucial. Prognosis for later reimplantation deteriorates rapidly—within minutes—if the tooth dries out, causing pulpal and periodontal damage. Storage media available to prevent drying, in order from most to least successful, are Hanks' balanced salt solution (a pH-balanced cell culture medium), Viaspan (used for preservation of transplant donor tissue), milk, physiologic (normal) saline, and saliva. An egg white may also be used. These fluids have an osmotic pressure similar to those of the pulp and periodontal tissues and therefore help preserve these structures. Tap water is not an appropriate storage medium because of its hypotonicity.

Although Hanks' solution, Viaspan, and milk are superior to saliva as storage media, the prevention of desiccation is much more important than waiting until Hanks' solution, Viaspan, or milk is available. If none of these is immediately available, the tooth can be stored in saliva. Perhaps the most readily available preservative other than saliva is fresh whole milk on ice (between 4° C and 20° C); however, parents, schools, teams, and facilities that sponsor sporting events now often have Hanks' solution in a kit. Hanks' solution has been shown to keep periodontal ligaments alive for 4 to 6 hours. Successful results have been reported with teeth suspended in Hanks' solution for up to 96 hours. It has also been found to restore cell viability in a tooth that has been avulsed for longer than 60 minutes. These kits contain a basket and net or a similar system to suspend, clean, and store the tooth in Hanks' solution while it is being transported for reimplantation (see Suppliers section). A basket allows the clinician to remove the tooth from the solution without touching it with fingers or forceps.

#### **INDICATIONS**

- Avulsed permanent tooth with minimal pulpal and periodontal damage, especially a tooth from the front of the mouth
- Tooth out of its socket for only a brief period of time
- Tooth stored in the proper physiologic medium

**NOTE:** One readily available source of saliva is the patient's mouth, and the tooth can be stored under the tongue. Another option is the mouth of a relative if the patient is unconscious or uncooperative. If stored in the patient's mouth, he or she needs to concentrate on not swallowing the tooth! Universal blood and body fluid precautions should be remembered if considering storing the tooth in someone else's mouth.

#### **CONTRAINDICATIONS**

- Primary (i.e., deciduous, milk, temporary) teeth should not be reimplanted. (Reimplanting these teeth may result in their fusion to the supporting bone and possible facial deformity. It may also damage or interfere with the development of the permanent teeth.)
- Avulsed teeth with gross caries or fractures should not be reimplanted.
- Patients with significant loss of periodontal support (periodontitis) should not have teeth reimplanted.

#### **EQUIPMENT**

- Adequate light
- Equipment necessary to follow universal blood and body fluid precautions (gloves, eye protection, mask)
- Sterile normal saline
- Irrigation syringe
- Local anesthetic (lidocaine with epinephrine), syringe (dental aspirating type or 3 mL), and 2-inch, 25- to 27-gauge needle

- Sterile  $2 \times 2$  inch cotton gauze squares or cotton rolls
- Nail file or emery board for tooth fracture, dental drill if available
- Tooth forceps
- Fraser suction catheter, suction source, and tubing
- Calcium hydroxide or zinc oxide and eugenol paste (protective and sedative for pulp; see Suppliers section) or toothpaste
- Dental dry foil or aluminum foil
- Small brush and cavity varnish (see Suppliers section) or clear nail polish
- Cold-curing periodontal pack (i.e., elastic quick setting dressing), dental utility wax, or beeswax (see Suppliers section)
- Applicator sticks (e.g., tongue depressor, wooden end of cotton swabs)
- Dental radiography equipment and supplies
- Penicillin VK 500-mg tablets (18 to 26 tablets) or clindamycin (parenteral antibiotics for those at risk; see Chapter 221, Antibiotic Prophylaxis)
- Hanks' balanced solution, a pH-balanced cell culture medium (optional is Viaspan, used to preserve transplant tissue)
- Tooth-saving system (optional, contains Hanks' balanced solution; see Suppliers section)
- Citric acid, 2% stannous fluoride, doxycycline syrup or suspension (optional, especially useful if a dentist is not available and tooth has dried more than an hour)
- Cyanoacrylate glue (optional, especially useful if a dentist is not available)
- Paper clip (optional, especially useful if a dentist is not available)

#### PREPROCEDURE PATIENT PREPARATION

Explain to the patient the procedure, possible complications, benefits, and the need for follow-up. The patient will need to remain still during the procedure, but discomfort should be minimal. Informed consent should be obtained.

**NOTE:** Immediate reimplantation (within 5 minutes) is one of the most critical factors related to periodontal healing. Unless stored in proper media, if the interval is more than 30 minutes before reimplantation, the success rate falls to less than 20% and the tooth inevitably requires endodontic therapy. If the patient or family member calls and is more than 5 minutes away from clinical care, an immediate attempt to reimplant the tooth provides the best outcome. Have the patient rinse the tooth under cold water or place it under his or her tongue for a few seconds, and then reimplant it at once. Instructions or words of encouragement may be needed. However, accident-associated factors such as the person's emotional state, a lack of knowledge of proper first aid, a lack of confidence by bystanders, or informed consent issues are often obstacles at the accident site. If these obstacles cannot be overcome, the only choice may be to store the tooth in the best medium available and to transport it and the patient to the clinic.

#### **TECHNIQUE**

1. If the tooth is stored in Hanks' solution, Viaspan, or milk on arrival, leave it in the medium. If it is stored in saliva or no media, place the avulsed tooth in Hanks' solution, Viaspan, or normal saline as soon as possible. If the tooth has been dry for from 20 to 60 minutes, it should be soaked in Hanks' solution for 30 minutes. If it has been dry for more than an hour, the periodontal cells are dead and the goal is to reduce root resorption. In that situation, dentists often recommend soaking the tooth for 5 minutes in each of three different solutions before reimplantation: citric acid, followed by 2% stannous fluoride, and finally doxycycline syrup or suspension. The tooth should not be merely discarded; attempts should be made to contact a dental professional for guidance.

- 2. If the patient is at risk for bacteremia, administer parenteral antibiotics.
- 3. Conduct a rapid medical history and systematic evaluation of the traumatized individual:
  - Where, how, and when did the trauma occur? Are there fractures?
  - Is there any neurologic damage? Unconsciousness? Amnesia? Headache? Nausea?
  - Are there any underlying medical conditions? Immunocompromise? Diabetes? Prostheses? Severe mitral valve prolapse? Heart murmurs? If any of these are life- or limbthreatening, they should be managed first. If not, make mental notes of other problems while rapidly preparing to reimplant the tooth.
- 4. When the patient is stable, administer local anesthetic to the socket area if necessary. The clinician should follow universal blood and body fluid precautions.
- 5. Perform a brief clinical examination:
  - Are there any other intraoral lacerations or disturbances?
  - Is the bite disturbed by other displaced teeth?
  - Make mental notes of these findings while rapidly preparing to reimplant the tooth.
- 6. Examine the tooth socket and flush with normal saline. Remove all clot material.

**NOTE:** Although flushing the socket is commonly suggested in practice guidelines, there is little scientific evidence to support this activity, so the socket should be manipulated as little as possible. (That is why reimplanting the tooth at the scene of the accident, if it can be accomplished within 5 to 10 minutes, is much more important than waiting to flush the socket or tooth.)

- 7. Remove the tooth from its soaking medium and, while holding the crown with gauze or tooth forceps, reimplant it as close as possible to its normal position, using finger pressure. *Do not touch the root*. The patient can assist the reimplantation by gently biting on gauze; this maneuver can also be used to help stabilize the tooth after reimplantation until more permanent stabilization can be arranged. Make sure the alignment is anatomic (remember that the curved side faces the tongue!). Observe the patient for malocclusion. If the tooth contacts another tooth with occlusion, it may be better to transport the tooth in preservation medium to a dental professional for definitive reimplantation.
- 8. Take a radiograph of the area, if possible.
- 9. Refer to a dentist for semirigid splinting and follow-up. If a dentist is unavailable, a cold-curing periodontal pack, aluminum foil wrapped over the tooth and the neighboring teeth, or dental wax or beeswax can act as a splint. For a more rigid splint, a small paper clip bent to conform to the buccal side of the neighboring teeth can be glued to the reimplanted tooth as well as two or three neighboring teeth with cyanoacrylate glue. The dentist can later remove the glue with a dental pick.
- 10. Immediately administer penicillin VK 1 g orally (for those not already given parenteral dose), then 500 mg orally four times a day for 4 to 6 days (clindamycin for those allergic to penicillin).
- 11. Administer tetanus toxoid if the patient has not had a booster within 5 years.

#### POSTPROCEDURE PATIENT EDUCATION

Nonsteroidal anti-inflammatory drugs and an occasional narcotic analgesic may be all that is necessary to manage the pain. The patient should avoid chewing in the area of the tooth; he or she should follow a soft diet and avoid extremes of temperature. Patients should be warned that any trauma to the tooth may cause pulpal necrosis or tooth resorption, regardless of management. For an avulsed tooth, inform the patient that the prognosis depends on the

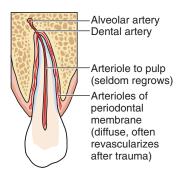

Figure 81-6 Blood supply to tooth.

length of time the tooth was out of the socket and the medium in which it was stored. Fortunately, a tooth has two sources of blood supply (Fig. 81-6). However, pulpal revascularization through the pulpal arterioles is almost nonexistent in teeth after complete root development (adult teeth). It is unusual even with immature root development. Periodontal ligament preservation is also infrequent, depending on the length of drying time to which the tooth was exposed. Fortunately, the periodontal ligament has a more diffuse blood supply and revascularizes more readily than the pulp. However, the importance of consulting a dentist for the appropriate follow-up care should be stressed, especially if further splinting is necessary.

#### **COMPLICATIONS**

- Necrosis of the pulp or periodontal ligament or complete loss of the tooth can occur. (Necrotic pulp tissue necessitates subsequent endodontic work.)
- An inadequately splinted tooth can remain loose, cause further damage to the attachment apparatus, and decrease the chance of tooth viability. If the tooth becomes dislodged it could result in aspiration.
- With a nonvital periodontal ligament, ankylosis or osteoclastic root resorption can occur, which requires a root canal.
- Localized infection or bacteremia can occur, but it is very rare.
- If avulsed teeth are unaccounted for, the possibility of aspiration or entrapment in soft tissues should be considered.

# TONGUE-TIE SNIPPING (FRENOTOMY) FOR ANKYLOGLOSSIA

Gary R. Newkirk • Mary Jane Newkirk

"Tongue-tie," or ankyloglossia, results from underdevelopment of the lingual frenum (frenulum) and occurs in nearly 5% of infants. Infants differ substantially in the degree to which their frenum attaches to the tongue. Most cases of tongue-tie are thought to resolve spontaneously by adulthood with little likelihood of feeding or speech development problems. However, the condition is often not noticed until later in life and has been associated with such symptoms as a speech defect (e.g., a lisp), dental problems with the lower teeth, and accumulation of food in the floor of the mouth. If noticed in an infant or child, parents are usually the ones to bring this to the clinician's attention (Fig. 82-1). The condition can easily be overlooked during the newborn examination because infants typically retract and roll the tongue downward when their mouth is open, which effectively hides the frenum from view. Furthermore, newborns rarely stick their tongues out for more than brief periods, so no one notices if the tongue cannot be protruded because of ankyloglossia.

Because tongue-tie is a fairly common and often unnoticed condition that lacks a precise definition, there are few formal outcome studies comparing infants having undergone frenotomy versus not. On one side of the debate, problems with sucking, breast-feeding, chewing, swallowing, dentofacial growth and development, gingival hygiene, and speech have been attributed to tongue-tie. On the other side, some researchers feel that the parents, not the child, have the problem. That is countered, again, by the fact that partial frenotomy, also referred to as tongue-tie snipping, remains a quick, easy, and safe procedure with benefits even if performed for cosmetic reasons or parental "dis-ease." Clinicians are more likely to perform partial frenotomy if they believe that ankyloglossia contributes to poor infant sucking and other breast-feeding problems, such as insufficient infant weight gain or sore nipples or recurrent mastitis in the mother. Simple frenotomy for infants and small children who have partial ankyloglossia can be performed safely in the outpatient setting.

The best method and timing for frenotomy remain debatable. When ankyloglossia *severely* interferes with lingual function (e.g., "frozen tongue"), few would argue the need for reduction, but in this case formal Z-plasty is necessary. The patient should be referred to an experienced surgeon because this procedure requires general anesthesia and sometimes a complicated reconstruction.

Anatomically, the frenum of the tongue is a triangular fold of mucous membrane extending back from the lower midline gingival tissue along the floor of the mouth and then arching to the midline of the undersurface of the tongue. The extent to which the tongue portion of the frenum extends along the undersurface to the tip of the tongue is variable. Tongue-tie occurs when the frenum (or an

abnormal portion of the frenum) continues distally toward the tip of the tongue so that the height/length of the frenum is so short that it prevents normal elevation or protrusion of the tongue.

#### **INDICATIONS**

Clinical evidence of short lingual frenum in an infant with resultant perceived speech problems or inhibited tongue protrusion, feeding, or swallowing.

#### **RELATIVE AND ABSOLUTE CONTRAINDICATIONS**

- Lack of clinical evidence or suspicion that ankyloglossia is a problem for the infant or child.
- Unstable medical conditions, such as a bleeding disorder (in many cases, this can be reversed).
- Evidence of dental or oral infection. (The procedure should be postponed until the infection is adequately treated or resolves.)
- Severe ankyloglossia, which requires frenectomy under general anesthesia. (Usually this procedure involves Z-plasty or a similar plastic surgery procedure.)
- Orofacial abnormalities. It is recommended that infants or children with ankyloglossia combined with other orofacial abnormalities be referred.

#### **EQUIPMENT**

- Straight or curved mosquito hemostat
- Surgical scissors (some clinicians prefer iris or other straight scissors, others use curved Metzenbaum scissors)
- Tongue retractor (e.g., small spoon, wooden tongue blade)
- Ice, ice chips, popsicle, or teething ring (optional)
- Topical anesthetic (e.g., viscous lidocaine, benzocaine [Cetacaine spray or Hurricaine syrup]) (optional)
- Infant restraint (e.g., swaddling sheets, circumcision or papoose board) (optional)
- Lidocaine with epinephrine, to control bleeding afterward (optional)

#### PREPROCEDURE PATIENT EDUCATION

Describe the risks to the parents, including discomfort; possible medication reaction (if used); recurrence of ankyloglossia during or after healing; injury to tongue or sublingual mucosa or tissue; infection; or bleeding. Parents may help by holding their small child in their lap and, while doing so, holding the child's head still and the

Figure 82-1 Ankyloglossia in a 2-week-old infant experiencing feeding difficulties.

child's mouth open. However, for newborns and infants—for the same reasons as for a circumcision—parents may want to leave the room. After examining the child, if more than one technique is possible, the clinician should explain the various techniques to the parents. Attempt to obtain their input on the desired technique. Parents should be aware that while performance of partial frenotomy may improve tongue function, it does not prevent all tongue, feeding, or speech problems.

#### **TECHNIQUE**

 With assistance as necessary, position or hold small infants or children in such a way that they will remain still. Wrapping an infant with sheets or a blanket is a very effective method of immobilization. Parents can still hold an infant that is "swaddled" in this manner in their lap. A "circumcision board" is effective if an assistant also stabilizes the head.

**NOTE:** Crying often improves exposure of the frenum.

- 2. Identify the frenum, the abnormal portion of the frenum (causing ankyloglossia), and the necessary degree of surgical lysis. A limited "snipping" of the lucent, membranous portion of the distal frenum is usually all that is required.
- 3. Many clinicians snip a lucent membranous or very thin fibrinous distal frenum without topical agents or the use of a hemostat, especially for infants younger than 4 months of age. While this technique may increase local bleeding, for a thin membrane there should be no more bleeding than when a child falls and bites his or her lip or tongue. This technique may also cause less overall trauma than with the use of a hemostat. If the child is old enough not to aspirate, have him or her suck on ice, ice chips, or a popsicle before and after the procedure for a certain degree of anesthesia and to minimize bleeding. Younger children may appreciate a frozen teething ring.
- 4. For a thicker or coarser frenum, topical anesthesia may be beneficial. For example, a cotton-tipped swab can be moistened in benzocaine syrup or sprayed with benzocaine (Fig. 82-2) and focally applied to the lower mouth and bottom of the tongue for

Figure 82-2 Spraying topical anesthetic on a cotton-tipped applicator.

Figure 82-3 Applying topical anesthetic to the frenum and surrounding

- excellent local anesthesia (Fig. 82-3). Viscous lidocaine or benzocaine spray can be applied directly to the area in the same manner. Mild sedation may also be beneficial (see Chapter 7, Pediatric Sedation and Analgesia).
- 5. If necessary, retract and gently elevate the tongue. A small spoon or wooden tongue blade with a slit fashioned in the end may be helpful.
- 6. As an option, with the tip of the mosquito clamp, grab and crush the frenum to the depth and at the position where the scissor snip will be made (Fig. 82-4A). After the discomfort from crushing the tissue has resolved, a certain degree of anesthesia is experienced in the crushed area.
- 7. Snip the crushed portion of the frenum (Fig. 82-4B). Warning: If tissue is snipped outside or beyond the crushed area of the frenum, it will result in more bleeding and pain.

NOTE: Although crushed tissue is somewhat anesthetized, a patient experiences some discomfort at the time of the crush. A child's immediate memory of pain as the result of an instrument being placed in the mouth may make it difficult to open the mouth again to snip the crushed frenum. This is why some clinicians perform the procedure by simply snipping (Fig. 82-5) without using a hemostat (especially when the frenum is very thin). However, for a thicker and coarser frenum, crushing the tissue with a hemostat will be necessary. For older children, there may be value in telling them that the painful part of the procedure is over after the hemostat has been applied and removed.

8. Use a dry cotton-tipped swab, or one moistened with 1% lidocaine with epinephrine, to control any bleeding or oozing. Ice, a popsicle, or a teething ring may also help control oozing. Figure 82-6 shows the appearance of the completed procedure.

#### SAMPLE OPERATIVE REPORT

See a sample operative report online at www.expertconsult.com.

#### POSTPROCEDURE PATIENT EDUCATION

- No special care of the surgical site is necessary.
- Ask the patient (or parent) to report significant bleeding or signs of infection.
- Instruct the parent to allow infants and children to resume normal feeding habits immediately.
- Ice chips, an ice cube, or a popsicle for children old enough to not aspirate, or a frozen teething ring for infants, may help stop any later bleeding or oozing.

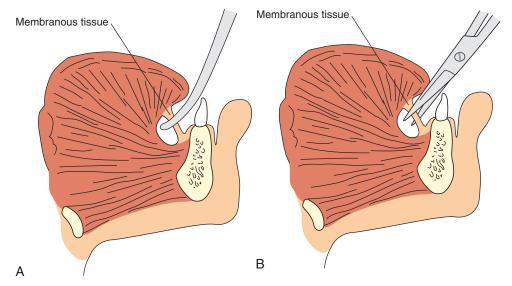

Figure 82-4 Tongue-tie snipping technique. A, Crush the abnormal portion of the frenum where the snip is to be made. B, Cut through the crushed area.

**Figure 82-5** Incising the abnormal portion of frenum (causing ankyloglossia) using curved Metzenbaum scissors.

**Figure 82-6** Appearance of the normal remaining frenum after partial frenotomy is completed.

- Ask the patient (or parent) to report any feeding difficulties or significant swelling.
- Inform the patient (or parent) to return for follow-up in 2 weeks, or sooner if complications arise.

## TONSILLECTOMY AND ADENOIDECTOMY

Thomas N. Told

Tonsillectomy is one of the oldest surgeries known. It was first described in 50 A.D. by Celsus, who used a hook to grasp the tonsil and his finger to excise the bulk of the tonsillar tissue. By the 6th century, hygienic concerns had led to the use of knives and other instruments to complete the surgery. These early surgeons were quick to recognize the importance of following the correct tissue planes to be successful, a fact that holds true today. The pain of doing surgery without anesthesia led to the development of instruments that would remove the tonsils quickly. These methods often failed to remove all the tonsillar tissue and obstruction would recur. Throughout the first half of the 20th century, tonsillectomy was performed under local anesthesia and later general anesthesia without airway protection. The procedure was often performed with very few indications in healthy individuals. Adenotonsillectomy reached its peak when 1.4 million procedures were performed in the United States in 1959.

Over the last 50 years the frequency of tonsillectomy and adenoidectomy has declined among American clinicians; however, it still remains the most common surgery performed on children younger than 15 years of age. There are many techniques and innovations that have been tried through the years, from snares to lasers. Many fell out of favor because of concerns over excessive blood loss, tissue damage, excessive postoperative pain, or extended intraoperative time.

This chapter focuses on three of the most popular techniques used today. These are cold knife and snare with or without electrocautery, harmonic ultrasonic scalpel (Ethicon Endosurgery), and bipolar radiofrequency ablation or Coblation (Arthrocare).

Most studies agree that the less heat introduced into the pharyngeal tissue, the less postoperative pain experienced by the patient. Cold knife and snare removal puts no heat into the system, but cold steel does nothing to stop the bleeding. Bleeding is the most feared complication of tonsillectomy, and electrocautery or sutures must be used as a supplemental measure to control the brisk bleeding. Electrocautery produces considerable heat at the operative site (400° C; Fig. 83-1A). Electrocautery and figure-of-eight sutures also cause collateral tissue damage for several millimeters around the bleeding site. This heat and tissue damage nullifies any benefits the cold knife procedure may have had with respect to lower pain levels or prompter healing rates. Both the harmonic ultrasonic scalpel and the radiofrequency Coblation wand cut and coagulate at the same time, resulting in very little blood loss. Hemostasis is achieved by the production of a protein plug in the end of the cut vessel from the ultrasonic or plasma energy of the devices. The harmonic scalpel generates operative site temperatures of 70° C to 80° C, and the radiofrequency Coblation wand produces a slightly lower temperature of 60° C (Fig. 83-1B). Less heat translates into slightly lower postoperative pain scores for the Coblator compared with the harmonic ultrasonic scalpel. However, recovery time is nearly identical, so the temperatures should not be a significant factor when deciding between these two techniques. All studies agree that lower pain scores and decreased recovery time also come from gentle and careful removal of all of the tonsillar tissue. Therefore, the best method for tonsillectomy is the technique with which the operating clinician is most comfortable, or has the most experience.

#### ANATOMY OF THE TONSIL BED

See Figure 83-2 for an overview of tonsil bed anatomy.

- Superior: soft palate
- Inferior: lingual tonsil
- Deep: superior constrictor muscle
- Anterior: palatoglossus muscle
- Posterior: palatopharyngeus muscle
- Vascular supply to the tonsil (Fig. 83-3)
  - Superior pole
     Ascending pharyngeal artery
    - Ascending pharyngeal arter Lesser palatine artery
  - Inferior pole
     Tonsillar branches of facial artery
     Dorsal lingual artery
     Ascending palatine artery

**NOTE:** The key to controlling brisk tonsillar bed bleeding is to direct efforts toward the superior or inferior poles first before trying to control every bleeder in the tonsillar bed because the poles are the vascular points of entry.

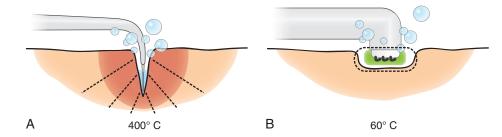

#### INDICATIONS FOR TONSILLECTOMY

#### **Absolute Indications**

- Hypertrophy resulting in obstructive sleep symptoms in adults or children that lead to adverse pulmonary or cardiovascular conditions
- Hypertrophy and airway obstruction leading to malformation of the facial bones or malocclusion of the teeth requiring dental attention
- Hypertrophy resulting in dysphagia and poor weight gain
- Recurrent peritonsillar abscesses requiring drainage that fail to heal with appropriately dosed medications (see Chapter 80, Peritonsillar Abscess Drainage)
- Tonsillitis that spawns febrile convulsions
- Tonsils that exhibit suspect growth or anatomic characteristics that may require biopsy for the exclusion of malignancy

#### **Relative Indications**

 Three or more documented episodes of acute tonsillitis within a year that result in lost time from work or school and require

**Figure 83-1 A,** Electrocoagulation produces excessive heat at the operative site and results in a wide area of thermal damage (400° C). **B,** The bipolar radiofrequency ablation (Coblation) wand and the ultrasonic cutting and coagulating instrument (harmonic scalpel) produce low heat (60° C) at the tissue interface while achieving good hemostasis. (Courtesy of ArthroCare ENT, Sunnyvale, Calif.)

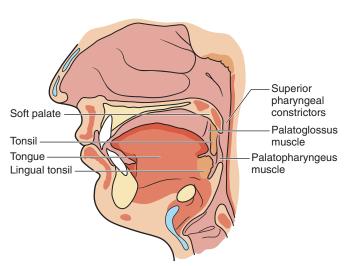

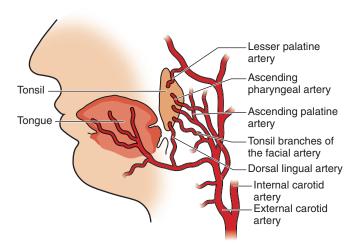

Figure 83-2 Anatomy of the tonsil bed.

**Figure 83-3** The tonsil is sustained by a rich supply of vessels that enter through the inferior pole. Only two branches enter the superior pole. Directing maximum hemostatic effort to the inferior pole controls most of the potential intraoperative bleeding.

treatment by a clinician. (Some clinicians recommend tonsillectomy in children who miss 2 or more weeks of school annually because of tonsillar infections.)

- Persistent episodes of a foul taste in the mouth or malodorous breath that do not clear with appropriate medical therapy.
- Chronic bouts of tonsillitis in a streptococcal carrier that do not respond to beta lactamase–resistant antibiotics.
- Nocturnal enuresis where upper airway obstructive sleep disorder also is present from large tonsils and adenoids.
- Attention deficit hyperactivity disorder resistant to treatment with coexistent upper airway obstructive sleep disorder.

## CONTRAINDICATIONS TO TONSILLECTOMY AND ADENOIDECTOMY

- Poor anesthetic risk
- Uncontrolled medical illness
- Anemia
- Acute bilateral infections
- Anticoagulated patient or patient with coagulopathy (either the anticoagulation/coagulopathy should be reversed or otolaryngology consulted)

## COMPLICATIONS OF TONSILLECTOMY AND ADENOIDECTOMY

- Hemorrhage during surgery, immediately in the postoperative period, or 5 to 7 days after surgery when the scabs slough off the adenotonsillar bed. Intraoperative bleeding around the endotracheal tube may form a clot and lead to airway obstruction after extubation. Swallowed blood can lead to postoperative nausea and vomiting.
- Dehydration.
- Temporary weight loss during the postoperative period.
- Perforation of the anterior or posterior tonsillar pillars, a benign complication.
- Airway obstruction.
- Death.
- Specific to adenoidectomy: nasopharyngeal stenosis and velopharyngeal insufficiency (nasal regurgitation of food and hypernasal speech).

**NOTE:** Patients with significant airway obstruction due to adenotonsillar hypertrophy may be at risk for postobstructive pulmonary edema syndrome once the obstruction is removed.

## PREPROCEDURE PATIENT EVALUATION AND CONSIDERATIONS

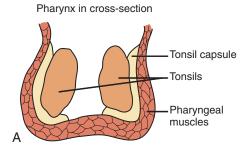

- Complete blood count, prothrombin time/international normalized ratio (INR), and bleeding time if there is a suspicion or a history of a bleeding disorder.
- Caution in children younger than 3 years of age, or with history
  of prematurity, seizures, neuromuscular conditions, or asthma,
  and in anyone with a significant history of obstructive sleep apnea
  or other severe medical conditions or extenuating circumstances.

**NOTE:** These patients may have to be monitored more closely in the postoperative period, and some may have to remain overnight to exclude delayed complications.

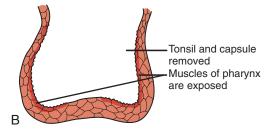

- Children with cardiovascular defects or heart murmurs must receive appropriate preoperative and postoperative antibiotic treatment.
- Evaluate and possibly remove extremely loose deciduous teeth that could be dislodged during the course of the surgery and threaten the airway.
- Patients should not eat solid foods for 8 hours before surgery.
- Intraoperative intravenous (IV) antibiotics such as ampicillin followed by a 1-week course of oral antibiotics have been shown to significantly reduce postoperative morbidity.
- Injection of local anesthetics into the tonsillar or adenoid beds at the start of surgery may decrease hemorrhage and improve postoperative recovery.
- Universal blood and body fluid precautions should be followed, whichever technique is performed.

#### **TYPES OF TONSILLECTOMY**

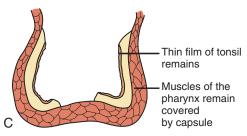

Figure 83-4 illustrates the two types of tonsillectomy.

Extracapsular tonsillectomy

Intracapsular tonsillectomy

**Figure 83-4 A,** The tonsil is separated from the pharyngeal muscle by a fibrous capsule. **B,** Extracapsular (subcapsular) tonsillectomy removes the tonsil and capsule, leaving the pharyngeal muscle to epithelialize in several weeks. **C,** Intracapsular tonsillectomy leaves the capsule and some tonsil attached. Tonsil regeneration is greater with this procedure.

#### Intracapsular (Tonsillotomy)

This method removes only the body of the tonsil down to the level of the capsular membrane, which remains in contact with the pharyngeal musculature. The tonsillar tissue is removed in small pieces using suction along with some type of tissue ablation, such as electrocautery, Coblation, or a harmonic scalpel. The incremental removal is useful when extremely friable tonsillar tissue will not allow grasping or traction with a tonsillar forceps to perform a subcapsular procedure. This procedure also theoretically decreases postoperative pain and recovery time. All the tonsillar tissue must be removed to reduce the risk of bleeding and recurrence.

#### Subcapsular

This technique is the favored method in use today. It involves the gentle traction and careful dissection of the tonsil and the capsule from the musculature surrounding the tonsillar bed. Using blunt cold dissection, dissection with the aid of a harmonic ultrasonic scalpel, or radiofrequency ablation, the entire tonsil with accompanying capsule is removed from the tonsillar bed. No redundant capsule or tonsillar tissue is left behind, reducing the risk of delayed complications.

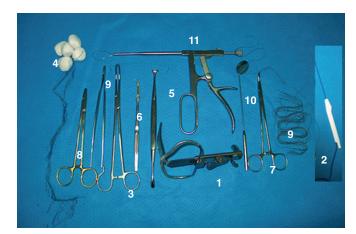

#### **COLD KNIFE AND SNARE METHOD**

This is the oldest and most widely recognized method of tonsil removal. Bleeding must be controlled by other means such as electrocautery, vasoactive topical agents, packing, or placement of absorbable sutures.

#### **Equipment**

See corresponding numbers in Figure 83-5.

- Self-retaining mouth gag and tongue retractor (1)
- Three sizes of tongue blades
- Operative suction and cautery (2)
- Curved tonsillar tenaculum (3)
- Posterior throat pack with attached retrieval string and small hemostat (4)
- Tonsil dissector and pillar retractor (5)
- Curved tonsil knife (6)
- Tonsillar bed hemostat (7)
- Needle holder (8)
- 0 or 2-0 plain gut suture on tonsil needle (9)
- Laryngeal mirror (10)
- Tonsil snare and wire (11)

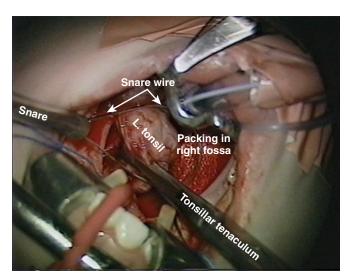

**Figure 83-5** Equipment for tonsil removal. See the "Equipment" section under "Cold Knife and Snare Method" for corresponding numbered parts.

#### **Technique**

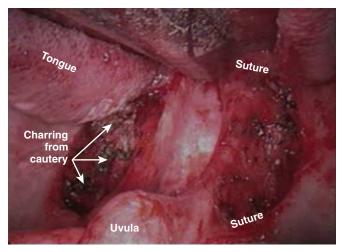

- The patient is placed supine on the operating table, and the head is hyperextended using a dropped headrest or a shoulder roll. The head must be secured on a donut-style headrest or on head pads.
- 2. The airway is protected by endotracheal intubation. A self-retaining mouth gag and tongue retractor is placed in the mouth to expose the tonsils. Exposure can be increased by suspending the handle of the tongue retractor from the Mayo stand. Some clinicians prefer to retract the soft palate with a small red rubber catheter placed through the nose and out of the mouth. It can then be secured over the mouth gag with a clamp; however, such a catheter is not always necessary for adequate exposure.

**NOTE:** The mouth gag and tongue retractor places pressure on the base of the tongue, so it should be released intermittently to restore circulation to the tongue and, it is hoped, reduce postoperative pain.

- 3. A throat pack is placed in the posterior pharynx. There should be a string or umbilical tape firmly applied to the pack for later retrieval. A hemostat is placed on the tape and left in place to ensure the pack is removed at the end of the procedure.
- 4. The tonsil is then grasped at its midpoint using a tonsillar tenaculum. Care should be taken not to grasp the anterior (palatoglossus muscle) or posterior pillars (palatopharyngeus muscle) when grasping the body of the tonsil. The tenaculum is used to apply medial traction on the tonsil, thereby tenting the tonsil into the tonsillar fossae and oral cavity.
- Begin the dissection superiorly. Using a curved tonsil knife, an incision is made down to the palatoglossus muscle along the posterolateral aspect of the muscle in the plane of the muscle fibers.
- 6. Using a tonsillar dissector, the tonsil is bluntly and gently dissected away from the bed and removed. The dissection should start from the superior portion of the tonsillar bed and work downward toward the lower one third or inferior portion of the tonsillar bed.
- 7. Leaving the inferior portion of the tonsil attached to the tonsillar bed, the snare is then applied. (The snare can then be applied over the tonsillar tenaculum's special handle [Fig. 83-6] or the tenaculum removed and then replaced through the loop of the snare.)

**Figure 83-6** The right tonsil has been removed and is packed. The left tonsil has been bluntly dissected from superior to medial, and the tonsil snare is being applied to clip off the inferior pole. Note the generous amount of bleeding in the throat and mouth. (Courtesy of Kevin T. Kavanaugh, MD.)

**Figure 83-7** If simple packing fails to control postoperative bleeding, then suture ligatures and suction cautery need to be used. The photograph shows the charring of conventional cautery on the left and the area on the right for most effective suture placement to control hemorrhage. (Photograph by Thomas N. Told, DO.)

- 8. The snare is now tightened slightly so that it nearly approximates the size of the body of the tonsil, but it is not yet tightened around the tonsil.
- 9. The tip of the snare is then moved to the back of the pharynx, to a point posterior to the body of the tonsil. The wire loop will be bent slightly inferiorly and medially relative to the body of the tonsil.
- 10. This snare is then closed briskly and firmly, which bluntly dissects the inferior portion of the tonsil away from the tonsillar bed. Bleeding will be brisk from the superior and inferior aspects of the tonsillar fossae. This can be controlled by placing packs into the bleeding tonsillar bed and waiting for the bleeding to stop. Applying figure-of-eight sutures to the superior and inferior aspects of the tonsillar fossae using 0 or 2-0 plain gut sutures on a tonsil needle may help with hemostasis. (Avoid placing the sutures too deeply, which could damage nearby structures, including blood vessels such as the carotid artery.) Unipolar or bipolar cautery, with or without suction, can also be used to ablate the bleeding areas (Fig. 83-7).
- 11. The procedure is repeated on the opposite side.

#### HARMONIC SCALPEL METHOD

This procedure requires the use of an ultrasonic generator that passes energy to a special titanium rod that vibrates at 55,000 times per second (Hz). This generates enough energy to vaporize tissue at the point of contact with the tip, and this can be limited to the width of a knife blade. The ultrasonic energy also generates enough heat (70° C to 80° C) to form protein plugs in the severed ends of blood vessels (Fig. 83-8).

There are two energy settings on the generator, a low setting (level 3) and a high setting (level 6). Unlike conventional electrocautery, where higher settings result in greater cautery power, the ultrasonic harmonic scalpel creates more hemostasis on the lower settings. The best setting for tonsillectomy is level 3.

The vapor that is generated from cell destruction helps undermine the tissue layers as well.

The tip is disposable and contains a blunt, curved back portion, a sharply hooked front, and large flat sides (Fig. 83-9). Most of the surgery is performed with the blunt, curved back part of the tip because it produces better bleeding control than the sharp, hooked front of the tip (see Fig 83-9). The large, flat side surfaces can also

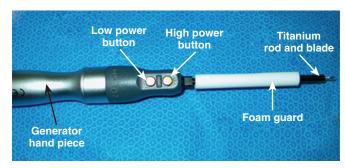

**Figure 83-8 A,** The ultrasonic generator forms a high-frequency sound wave that is transmitted to the handpiece, where it causes a titanium rod to vibrate at 55,500 Hz. **B,** A special torque wrench ensures proper fit between handle and titanium rod to prevent loss of energy. (Courtesy of Ethicon Endo-Surgery, Inc., Cincinnati, OH.)

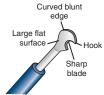

be used for hemostasis in areas like the superior and inferior tonsillar poles where the major blood vessels enter. The sharp, hooked portion of the front of the blade can be used to divide the nonvascular membranes or the thick, tough tissue that has been cauterized by the curved back part of the tip. Although the harmonic scalpel can control the usual bleeding that occurs during the course of a normal procedure, other measures such as unipolar cautery or sutures may be required to control larger, more brisk bleeders that cannot be occluded by the harmonic scalpel tip.

#### **Equipment**

See the corresponding numbers in Figure 83-10.

- Harmonic scalpel generator and disposable hooked dissection tip (1)
- Self-retaining mouth gag and tongue retractor (2)
- Three sizes of tongue blades (3)
- Curved tonsillar tenaculum (4)
- Posterior throat pack with attached retrieval string and small hemostat (5)
- Operative suction and cautery (6)

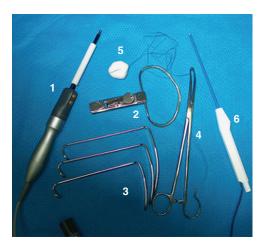

**Figure 83-9** Heat can be generated along the rod, so a foam guard covers the rod where it could touch lip and other mouth parts. High power cuts quickly but gives less hemostasis. Low power controls bleeding the best. *Bottom, Magnified view of the hooked blade shows the operative surfaces.* (Courtesy of Ethicon Endo-Surgery, Inc., Cincinnati, OH.)

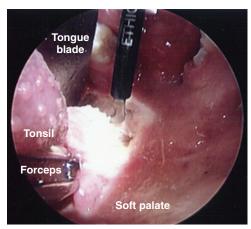

- Laryngeal mirror
- Sucralfate liquid
- 0 or 2-0 plain gut tonsil suture, and curved, long-handled needle holder on standby

#### **Technique**

- 1. The patient is placed supine on the operating table with the neck hyperextended and the head secured.
- 2. The airway is protected by endotracheal intubation. A self-retaining mouth gag and tongue retractor is placed in the mouth, exposing the tonsils. Exposure can be increased by suspending the handle of the tongue retractor from the Mayo stand. Some clinicians prefer to retract the soft palate with a small red rubber catheter placed through the nose and out of the mouth. It can then be secured over the mouth gag with a clamp; however, such a catheter is not always necessary for adequate exposure.
- The body of the tonsil is grasped with the tonsillar tenaculum and retracted medially into the tonsillar fossae/oral cavity. This will tent the palatoglossus muscle and accentuate the boundaries of the tonsillar body.
- 4. The dissection begins near the boundary of the palatoglossus muscle with the anterior aspect of the body of the tonsil.
- 5. Using the blunt, curved back portion of the tip as a scalpel (see Fig. 83-9), and extremely light downward pressure, the tip is

**Figure 83-10** Harmonic scalpel method equipment. See the "Equipment" section under "Harmonic Scalpel Method" for corresponding part numbers. (Courtesy of Ethicon Endo-Surgery, Inc., Cincinnati, OH.)

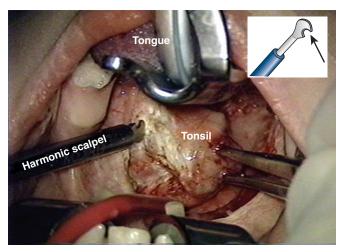

**Figure 83-11** Dissection of the middle and superior portion is done with the blunt, curved side of the hooked blade. The traction on the tonsil clamp is in the direction opposite to the plane being operated. Note the white hemostatic capsular plane under the scalpel. *Bottom,* The curved edge (*arrow*) is the best dissector and is used to do most of the procedure. (Photograph by Thomas N. Told, DO.)

energized and moved back and forth a few millimeters each way. Proceed slowly and carefully to deliver the tonsil (Fig. 83-11).

- 6. There will be some vapor and foam released by the tip. This vapor tends to separate the tissue planes and make the dissection easier. The capsular tissue under the tip will turn white to slightly brown; it is important to stay in this plane. The tonsillar capsule will remain a white and glistening membrane, whereas the delivered tonsil will have an egglike appearance. Continue this maneuver in a lateral and inferior or superior direction until the entire anterior portion of the tonsil is released.
- 7. If the tip of the harmonic scalpel penetrates the body of the tonsil, the tonsillar tissue will bubble up with the appearance of fresh-cooked oatmeal. If this happens, change the direction and pressure of the tip slightly until you again enter the correct plane.
- 8. The dissection can then proceed inferiorly or superiorly, depending on which direction the tonsil releases easiest from the bed.
- 9. The tonsillar tenaculum can be manipulated and twisted to more easily expose the different surfaces of the tonsil (Fig. 83-12).
- 10. The largest vessels enter the tonsil from the inferior aspect of the tonsillar bed near the lingual tonsil. When dissecting this area, most clinicians use the larger, flat side of the harmonic scalpel tip to create a greater area of hemostasis and less bleeding (Fig. 83-13).
- 11. When the body of the tonsil is completely released from the superior or inferior tonsillar bed, the tenaculum can then be reapplied to facilitate removal of the tonsil from the palatopharyngeus muscle of the posterior pillar.

**NOTE:** When removing the tonsil body from the muscle where tissue planes have been destroyed by infection, it is important to confine the dissection to the tonsillar side rather than the muscular side.

12. When the tonsil is completely removed, residual bleeding can be controlled by placing the flat portion of the dissection tip against the bleeding site and gently tamponading the bleeding. The tip can be placed on low power for 10 seconds to coagulate the bleeding. Small amounts of capillary bleeding can also be

**Figure 83-12** The sharp, hooked portion of the harmonic scalpel is not frequently used because it cuts too rapidly to provide effective hemostasis. It is best used on thin tissue in the superior portion of the tonsil, or to cut tough, thick capsule. *Inset:* The sharp, hooked blade (*arrow*) can be used to do fine dissection or transect large avascular tissue.

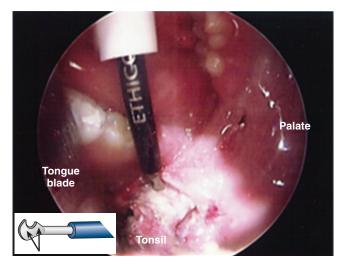

controlled by lightly moving the activated tip over the bleeding site until the bleeding stops or a light char appears.

**NOTE:** When controlling bleeders, it is important that the clinician be very careful not to apply excessive downward pressure to the tip because it will quickly bury the tip into deeper layers and cause serious bleeding.

- 13. The procedure is repeated on the opposite tonsil.
- 14. The tonsillar beds are painted with sucralfate liquid, and the self-retaining retractor released to check for any residual bleeding. The posterior throat pack is removed and the posterior pharynx is then thoroughly suctioned, if necessary.

#### **COBLATION METHOD**

This technique is the favorite for many surgeons because it is relatively fast and produces less heat and pain, all leading to shorter recovery times. The wand in this unit contains both suction and

**Figure 83-13** The flat portion of the hooked blade is used on the inferior aspect of the tonsil near the tongue blade, where the major blood vessels enter. This achieves maximum hemostasis. Extremely large vessels are gently compressed with the large, flat surface of the blade and power applied for 5 to 10 seconds. *Inset*: The flat surface of the blade (*arrows*) provides the best hemostasis. (Photograph by Thomas N. Told, DO.)

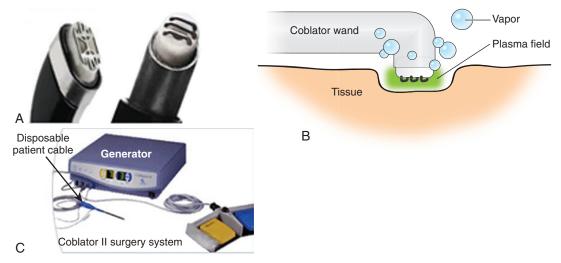

Figure 83-14 The Coblation wand contains both suction and bipolar cautery (A). It produces tissue vaporization by passing a bipolar radiofrequency current through normal saline (B). The Coblator is the only device that can do both tonsillectomy and adenoidectomy (C). (Courtesy of ArthroCare ENT, Sunnyvale, Calif.)

bipolar cautery. It produces tissue vaporization by passing a bipolar radiofrequency current through normal saline (Fig. 83-14A). This results in the production of a plasma field of sodium ions (Fig. 83-14B). This plasma field is able to vaporize tissue at low temperatures (60° C) and coagulate blood in any severed vessels. As previously mentioned, the instrument possesses a built-in suction feature that removes excess water and blood. Larger vessels that are not controlled with the plasma field can be cauterized with the built-in electrocautery. Set the electrocautery feature on the lowest settings that will work to avoid collateral tissue damage. The Coblator is the only device that can do both tonsillectomy and adenoidectomy (Fig. 83-14C). The power of the Coblator's plasma field also can be varied so that the operator can perform either dissection or ablation.

The Coblation wand is more than twice the diameter of the harmonic scalpel, but its curved tip makes it easy to use. Like the harmonic scalpel, the Coblation wand must be used slowly and carefully during dissection for the best results. This device can also perform either an intracapsular or a subcapsular tonsillectomy without requiring extra equipment.

#### **Equipment**

See Figure 83-10 for pieces 2 through 5.

- Bipolar radiofrequency Coblator unit and wand (see Fig. 83-14C)
- Self-retaining mouth gag and tongue retractor (2)
- Three sizes of tongue blades (3)
- Curved tonsillar tenaculum (4)
- Posterior throat pack with attached retrieval string and small hemostat (5)
- Laryngeal mirror
- Sucralfate liquid

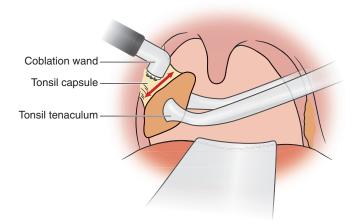

#### **Technique**

- The patient is placed supine on the operating table with the neck hyperextended and the head secured.
- 2. The airway is protected by endotracheal intubation. A self-retaining mouth gag and tongue retractor is put in place and, if necessary, suspended from the Mayo stand to increase exposure.
- The tonsil is grasped with a tonsillar tenaculum and retracted medially.
- 4. The tip of the wand is used to carefully dissect the anterior portion of the tonsil away from the surrounding muscle. The tip of the wand is always pointed toward the tonsillar tissue to

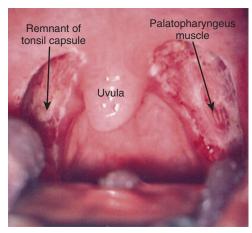

- prevent injury to underlying tissue (Fig. 83-15). The tonsil is manipulated to expose the lateral and inferior surfaces to the tip of the wand.
- Larger vessels are point cauterized with the electrocautery feature. Care must be taken to use the lowest setting to avoid excess tissue damage.
- 6. The procedure is repeated on the opposite tonsil.
- 7. The tonsillar fossae are painted with sucralfate solution.
- 8. The mouth gag is released and the beds are inspected for bleeding.
- 9. The posterior throat pack is removed and the posterior pharynx is suctioned, if necessary.
- 10. Both fossae are inspected for the presence of any tonsil tissue (Fig. 83-16).

#### **INDICATIONS FOR ADENOIDECTOMY**

- Large adenoids causing upper airway obstruction and resulting in obstructive sleep apnea.
- Children with large adenoids, with or without large tonsils, resulting in snoring and mouth breathing.

**Figure 83-15** The Coblation wand uses a sodium ion cloud at the tissue interface to cut tissue and coagulate blood vessels. Bipolar cautery is also provided to coagulate large bleeding vessels. The wand also contains a suction tip that removes vapor and blood obscuring the operative field. Traction is maintained in an opposing direction to the wand, which aids in separating the tissue planes. (Courtesy of ArthroCare ENT, Sunnyvale, Calif.)

**Figure 83-16** Photograph showing the pharynx with both tonsils ultrasonically removed, exposing the posterior tonsil pillars with a thin film of capsule and exposed palatopharyngeus muscle. Note the absence of the charring usually present with conventional electrocautery. (Courtesy of ArthroCare ENT, Sunnyvale, Calif.)

**NOTE:** There is no evidence that adenoidectomy improves chronic otitis media; therefore, its use is *discouraged* for this condition.

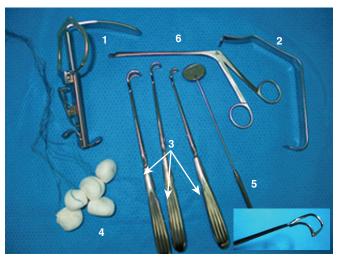

#### **CONTRAINDICATIONS TO ADENOIDECTOMY**

Only conservative adenoidectomy should be performed in the presence of occult submucous cleft palate; therefore, both the hard and soft palates should be examined visually and manually for a cleft palate.

#### **EQUIPMENT**

See the corresponding numbers in Figure 83-17.

- Self-retaining mouth gags and tongue retractor (1)
- Palate retractor (2)
- Adenoid curettes (3)

**Figure 83-17** Adenoid curettes come in three widths, and care must be taken to choose one that is not too wide. A curette that is too wide may injure the opening to the eustachian tube adjacent to the adenoid tissue. Adenoid tissue around the eustachian tube can be removed with the punch adenotome. See the "Equipment" section under "Adenoidectomy" for corresponding part numbers. *Inset*: Curette blade. (Photograph by Thomas N. Told, DO.)

- Punch adenotome (6)
- Posterior throat pack with attached retrieval string and small hemostats (4)
- Laryngeal mirror (5)
- Suction cautery (optional)
- Nasal suction catheter of appropriate caliber
- Coblation equipment and wand (for coblation method)

#### **TECHNIQUE**

#### **Curette Method**

- 1. A self-retaining mouth gag is placed in the mouth and suspended from the Mayo stand.
- 2. The hard and soft palates are inspected visually and manually for occult submucous cleft palate. If there is no cleft palate, the soft palate is then retracted with a red rubber catheter that is placed through the nose and out the mouth and clamped over the retractor to expose the adenoid bed.
- 3. The adenoid bed is inspected with the laryngeal mirror for the presence of adenoid tissue. Adenoid tissue decreases with age and is often gone by the teenage years.
- 4. An adenoid curette is placed on the adenoid tissue extending superior to the soft palate. It is placed high in the nasopharynx, basically abutting the posterior aspect of the nasal septum.
- 5. Downward pressure is applied to the curette while the curette is moved along the plane of the posterior pharyngeal muscle (Fig. 83-18). Take care not to penetrate deeply into the prevertebral tissue.
- 6. The bulk of the adenoid tissue is removed with the first pass.
- Occasionally a second pass may be needed with grossly enlarged adenoids. Take care not to venture too far laterally to avoid injuring the torus tubarius or eustachian tube opening.

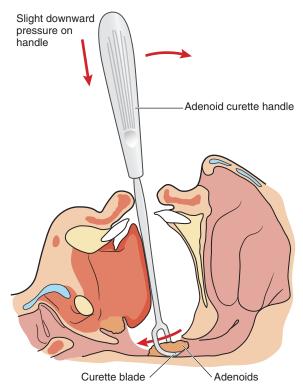

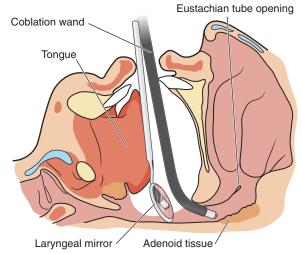

Figure 83-18 The handle of the adenoid curette moves back slightly as the blade moves forward, curetting the tissue. Slight downward pressure is applied to keep the blade in contact with the posterior pharyngeal wall.

**Figure 83-19 Coblation adenoidectomy.** (Courtesy of ArthroCare ENT, Sunnyvale, Calif.)

- 8. Redundant tissue around the opening of the eustachian tube can be carefully removed with a punch adenotome.
- A nasal suction catheter is inserted and continuous suction is applied for 2 to 3 more minutes, until bleeding stops. Nasopharyngeal packing may also help.
- Rarely does this technique produce enough bleeding for cautery to be required. Persistent postoperative oozing may be controlled somewhat by nasal decongestant drops.

#### **Coblation Method**

- Patient preparation and exposure are the same as with the curette method.
- The soft palate is retracted with a red rubber catheter placed through the nose and out the mouth and then clamped over the retractor to expose the adenoid bed.
- 3. Using a laryngeal mirror, the area to be ablated is inspected.
- 4. The Coblator is set on level 6 or 7 and the tip of the wand is energized. The tissue is removed to the level of the pharyngeal muscle (Fig. 83-19). Take care not to venture too far laterally, which increases the risk of injury to the openings of the eustachian tubes on both sides of the pharynx.
- Bleeding can be controlled with the built-in electrocautery feature.

## POSTPROCEDURE EVALUATION AND ORDERS AFTER TONSILLECTOMY AND ADENOIDECTOMY

- Most procedures can be done in same-day surgery.
- Continue IV maintenance fluids until the patient tolerates oral fluids.
- Oral fluids can be started after surgery when the patient is awake enough to protect the airway.
- Some children benefit from postoperative ice collars and cool mist vaporizers.
- Nausea can be controlled with promethazine 12.5 to 25 mg IV every 4 to 6 hours in adults or 0.25 to 1 mg/kg IV every 4 to 6 hours in children. Ondansetron (Zofran) 6 to 8 mg IV every 6 hours in adults and 0.15 mg/kg IV every 4 to 6 hours in children also works well.
- Give IV analgesics such as meperidine 25 to 50 mg IV every 3 hours in adults, and 0.25 to 0.5 mg/kg IV every 3 hours in children for severe pain.

- Morphine sulfate 2.5 to 10 mg every 2 to 4 hours in adults, 0.05 to 0.2 mg/kg every 4 hours in children, also can be given for severe pain.
- If the patient can tolerate oral fluids, give acetaminophen/hydrocodone 500/7.5/15 mL 2.5 to 5 mL orally every 4 hours to children, and 10 to 15 mL orally every 4 hours to adults.
- The role of sucralfate to reduce pain in the postoperative period is still debated, but 1 teaspoon orally four times a day can be of benefit in both children and adults.
- Dexamethasone elixir 0.03 to 0.3 mg/kg/day in children, 0.75 to 9 mg/day in adults, divided into two doses can be used in the postoperative period to reduce swelling and nausea. Given in the immediate postoperative period, dexamethasone is probably of greatest benefit to those patients at risk of laryngeal edema or airway obstruction. In other patients, it may be of benefit to wait until the third postoperative day, when most patients seem to suffer the greatest discomfort. Instituting oral dexamethasone for 3 or 4 days during this time can reduce pain and increase oral intake, and is relatively free of side effects.
- Amoxicillin given orally for 1 week after surgery has been shown to decrease morbidity.
- Children who cannot tolerate oral opioids usually do very well on regular doses of acetaminophen, but they should avoid all aspirin or nonsteroidal anti-inflammatory drug (NSAID) containing products.
- Adults who can tolerate oral tablets can be sent home on oral analgesics that contain no aspirin or NSAIDs.

## Ambulatory Blood Pressure Monitoring

Russell D. White • Thomas H. Mitchell

Ambulatory blood pressure monitoring (ABPM) is an automated, noninvasive technique for obtaining blood pressure measurements at predetermined intervals over an extended period of time (usually 24 hours or more) while the patient goes about his or her daily activities. The process involves attaching a measuring and recording device to the patient. These devices are lightweight and use either the auscultatory (i.e., microphone and Korotkoff's sounds) or the oscillometric method (i.e., senses arterial waves) to determine blood pressure. Although the auscultatory method needs low ambient noise levels to obtain its most accurate results, it tolerates patient movement better than the oscillometric method. In contrast, although the oscillometric method tolerates high levels of environmental noise, it is most accurate when the patient is less physically active. The recordings can be downloaded for analysis.

Hypertension has traditionally been defined as an office systolic blood pressure of 140 mm Hg or higher and diastolic blood pressure of 90 mm Hg or higher; however, it is now defined at lower levels for patients with diabetes or target organ damage (e.g., left ventricular hypertrophy, heart failure, angina or prior myocardial infarction, prior coronary revascularization, stroke or transient ischemic attack, dementia, chronic kidney disease [glomerular filtration rate <60 mL/min], peripheral arterial disease, retinopathy), and elevated systolic blood pressure is frequently isolated (i.e., elevated in the absence of elevated diastolic blood pressure). Over 50 million Americans are hypertensive, a major risk factor for such common diseases as cardiovascular disease, stroke, aortic aneurysm rupture, renal failure, and retinopathy. Because some patients are hypertensive only during specific hours of the day, documentation of adequate blood pressure control over 24 hours is imperative to prevent sequelae. Studies have shown that hypertension diagnosed with ABPM more often correlates with target organ damage than hypertension noted on sporadic blood pressure measurements in the office setting (especially in patients with albuminuria or echocardiographically determined left ventricular hypertrophy). Patients whose average pressures by 24-hour ABPM are greater than 135/85 mm Hg have twice the risk for a cardiovascular event compared with those with 24-hour mean blood pressures less than 135/85 mm Hg, regardless of the blood pressures measured in the office. In most people, blood pressure decreases by 10% to 20% at night; those without such a reduction (i.e., nondippers) are at increased risk of cardiovascular events. Conversely, overtreatment of hypertension can lead to complications such as transient hypotension, dizziness, and myocardial ischemia. In addition, as many as 21% of patients with mild blood pressure elevation in the office are incorrectly diagnosed with and treated for hypertension. Likewise, although having the patient monitor his or her blood pressure at home (i.e., self-monitored blood pressure) can improve blood pressure control, it has been difficult to correlate such a practice with fewer cardiovascular events. Therefore, ABPM offers an alternative to both office and home blood

pressure measurements, facilitating both the diagnosis and the management of hypertension.

#### **INDICATIONS**

Routine sporadic blood pressure measurements in the office setting remain the recommended method to screen for and monitor hypertension. ABPM should not be used indiscriminately as a screening device. However, because blood pressure measurements in the office can lead to both false-positive and false-negative results, ABPM can be useful for finalizing the diagnosis. Figure 84-1 provides a helpful algorithm. Indications may include the following:

- Normal or borderline office hypertension with target organ damage (defined by the American Heart Association [AHA] and the National Institutes of Health [NIH] Joint National Committee's [JNC] Seventh Report as left ventricular hypertrophy, heart failure, angina or prior myocardial infarction, prior coronary revascularization, stroke or transient ischemic attack, dementia, chronic kidney disease [glomerular filtration rate <60 mL/min], peripheral arterial disease, retinopathy)
- Persistent office hypertension without target organ damage
- Discrepancy between office and home blood pressure measurements (especially in diabetic and elderly patients)
- Considerable blood pressure variability found during same office visit or over different visits
- Episodic hypertension (e.g., smoking raises blood pressure acutely, and the level returns to baseline about 15 minutes after stopping)
- Episodic angina or pulmonary congestion unrelated to exercise
- Determination of the duration or efficacy of antihypertensive medications during the 24-hour treatment cycle
- Dosage adjustment of antihypertensive medications
- Documented hypertension unresponsive to treatment ("drug resistance")
- Suspected pressor ("white coat") hypertension and no target organ damage
- Office blood pressure elevated during pregnancy and preeclampsia suspected
- Autonomic dysfunction
- Hypotensive symptoms while on antihypertensive medication
- Evaluation of syncope or pacemaker syndromes

#### **CONTRAINDICATIONS AND LIMITATIONS**

- Cost: some insurance companies may not reimburse for ABPM
- Irregular, rapid heart rate: limits ability to obtain blood pressure measurements and limits the accuracy of ABPM
- Severe obesity: limits ability to obtain blood pressure measurements and limits the accuracy of ABPM
- Severe patient anxiety regarding instrument

#### Ambulatory blood pressure monitoring

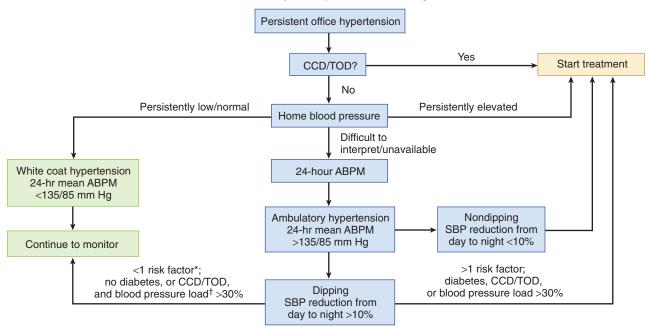

Figure 84-1 Algorithm for appropriate use of ambulatory blood pressure monitoring (ABPM). CCD, clinical cardiovascular disease; SBP, systolic blood pressure; TOD, target organ damage. \*Major cardiovascular risk factors in patients with hypertension (Joint National Congress VI) include smoking, dyslipidemia, diabetes, age older than 60, gender (men and postmenopausal women), and family history of early cardiovascular disease. †The proportion of blood pressures during the monitoring period that are increased relative to preset thresholds (140/90 mm Hg awake, 120/80 mm Hg asleep). (Updated from Ernst ME, Bergus GR: Ambulatory blood pressure monitoring: Technology with a purpose [editorial]. Am Fam Physician 67:2262–2263, 2003; with permission.)

#### PREPROCEDURE PATIENT PREPARATION

The procedure should be explained to the patient as well as its risks, benefits, and any alternatives. Obtain either verbal or written consent. Patients should be instructed to record any symptoms or events that occur during the monitoring period and any medications they are taking (and when they take them). In most cases, they should be instructed not to speak or move during cuff deflation (recording phase). Patients should also usually avoid strenuous activity (e.g., running or racquet sports) during the study. They should know how long they will be monitored, where to go to have the equipment removed, and when they might expect the results. If not contraindicated, the clinician may choose to offer the patient a sleep medication to minimize the equipment's interference with sleep.

#### **EQUIPMENT**

- Monitor (with instructions) for ABPM
- Automatic blood pressure cuff and sphygmomanometer
- Connectors and tubing
- 24-hour diary for events, activities, and medications

#### **TECHNIQUE**

- 1. The clinician should follow the manufacturer's instructions for attaching the equipment and performing the procedure. However, this usually means placing the microphone/sensor over the brachial artery proximal to the elbow of the nondominant arm (Fig. 84-2). Proper positioning of the microphone/sensor is critical.
- 2. Select the appropriate cuff size. The bladder inside the cuff should encircle 80% of the upper arm circumference without overlap.
- Attach and secure the automatic cuff to the upper arm. To prevent shifting of the cuff on the arm, an adhesive-backed strap is usually placed on the arm. The cuff is then placed around the

- arm and secured to the adhesive-backed strap, often by snapping it in place.
- 4. Connect the cuff-microphone/sensing unit to the monitor.
- 5. The connecting tubing is passed under upper body clothing to the monitor worn on the waist in a carrying pouch.
- 6. Calibrate the monitor for each patient in the lying, sitting, and standing positions. Measure blood pressure simultaneously with a manual cuff and sphygmomanometer or sphygmomanometer attached to the monitor through a T-tube device. (Three consecutive measurements should be within 3 to 5 mm Hg of one another.)
- 7. Secure the hose and microphone/sensor cable in a manner that will minimize patient discomfort.
- 8. Set the frequency of recordings. (Typical is three to four times per hour during waking hours and one to two times per hour during sleeping hours.)
- 9. Instruct the patient to record any symptoms or events, his or her activities, and which medications were taken and when they were taken during the monitoring period.
- 10. Instruct the patient to not speak or move during cuff deflation (i.e., recording phase).

Figure 84-2 Placement of ambulatory blood pressure monitoring unit.

- 11. Instruct the patient to avoid strenuous activity (e.g., running or racquet sports) during the study.
- 12. Remove the monitoring and recording device at the end of the study period and retrieve the recorded data.

#### **COMPLICATIONS**

- Inaccurate or incomplete results
- Interference with normal sleep patterns
- Inconvenience related to device
- Petechiae at measurement site
- Arm edema distal to cuff
- Transient arm discomfort
- Dermatitis
- Ulnar nerve palsy (rare)

#### INTERPRETATION OF RESULTS

Information acquired from ABPM normally includes (1) average blood pressures (usually average systolic, diastolic, and mean blood pressures); (2) diurnal fluctuations in blood pressure; and (3) short-term variability of blood pressure.

Most normotensive individuals exhibit a circadian pattern of blood pressure, reaching a peak during the daytime hours and a nadir after midnight (however, shift workers may reverse this pattern). Hypertensive patients also usually follow this diurnal pattern, with (as mentioned previously) an average blood pressure greater than 135/85 mm Hg when awake and greater than 120/75 mm Hg during sleep. Blood pressure usually increases after awakening and with increased activity in the early morning. Staessen and colleagues (1991) reviewed several studies and summarized average diurnal blood pressures (Table 84-1). Combining these data with the criteria of the JNC 7 report (Chobanian et al., 2003), the 2007 European Society for Hypertension–European Society for Cardiology guidelines (Table 84-2), and other data, the following diagnostic criteria are suggested:

- Hypertension is diagnosed if more than 30% of the 24-hour systolic readings are greater than 140 mm Hg, or greater than 90 mm Hg for diastolic readings (Fig. 84-3). This is an abnormal blood pressure load (percentage of elevated systolic and diastolic pressures during a 24-hour period). In patients with diabetes or target organ damage, hypertension should be diagnosed if more than 30% of the 24-hour systolic readings are greater than 130 mm Hg, or greater than 80 mm Hg for diastolic readings.
- Average systolic arterial pressure greater than 130 mm Hg or average diastolic pressure greater than 80 mm Hg is considered hypertension. Also, daytime average systolic pressure greater than 135 mm Hg or daytime average diastolic pressure greater than 85 mm Hg, or night-time average systolic pressure greater than 120 mm Hg or night-time average diastolic pressure greater than 70 mm Hg is considered hypertension (2007 European Society for Hypertension–European Society for Cardiology guidelines).
- A nondipper is diagnosed if the patient's blood pressure does not decrease by at least 10% at night. If the patient is being treated

TABLE 84-1 Average Normal Ambulatory Blood Pressure Monitoring Values

	Day	Night	24-Hour
Average blood pressure (mm Hg) Systolic range (mm Hg)	123/76 101–146	106/64 86–127	118/72 97–139
Diastolic range (mm Hg)	61–91	48–79	57–87

### **AMBULATORY PHLEBECTOMY**

Karl S. Hubach

The treatment of venous disease has undergone considerable change in the past two decades. Ambulatory phlebectomy (AP) remains popular as a surgical means of removing large varicose veins. This chapter introduces the basic techniques and ideas behind AP, which is an in-office surgical technique used to remove varicose veins through multiple small incisions. It is performed using only a local anesthetic and yet provides excellent cosmetic and functional results. When the compression bandage is in place, ambulation is allowed immediately after the procedure. Because the highest (most proximal) point of reflux in the venous system must be corrected for AP to remain successful, AP is frequently done in conjunction with another procedure such as junctional ligation, ultrasonographyguided sclerotherapy, an ablation procedure with laser or radiofrequency, or venous stripping (see Chapter 86, Endovenous Vein Ablation, and Chapter 92, Sclerotherapy).

Benefits of AP include the following:

- It is performed in an outpatient setting.
- It is a convenient, safe, and cost-effective treatment for varicose veins.
- The patient is able to walk out of the office following the procedure with little to no change in his or her level of activity.
- The rate of complications is extremely low.
- The procedure can be performed without hospitalization or general anesthesia and it allows for a return to normal activity; thus the expense to the patient and the health care system is markedly reduced.

Therefore, AP provides an excellent addition to the total care and treatment of varicose veins and venous disease.

#### **INDICATIONS**

- To remove veins of most sizes for symptomatic or cosmetic reasons
- Primarily used for the removal of symptomatic, visible varicose veins of the lower extremities

#### **CONTRAINDICATIONS**

#### **Absolute**

- Known metastatic carcinoma
- Allergy to the local anesthetic
- Hypercoagulable or hypocoagulable state
- Severe arterial occlusive diseases (see Chapter 88, Noninvasive Venous and Arterial Studies of the Lower Extremities)
- Hemodynamically important secondary varicosities
- Poor general health
- Incapacitated elderly patient
- CREST syndrome (calcinosis, Raynaud's phenomenon, esophageal involvement, sclerodactyly, and telangiectasia) involving the lower extremities

#### Relative

- Superficial thrombophlebitis
- Bacteremia and certain other blood-borne infectious diseases
- Pregnancy
- Coagulopathies
- Propensity to keloid formation
- Significant fibrosis of the vein
- Acute deep venous thrombosis
- Overlying infection or significant skin compromise
- Deep venous insufficiency

#### **EQUIPMENT AND SUPPLIES**

- Camera
- Surgical marking pen
- Vein transilluminator (e.g., Veinlite)
- 10-mL syringe with a 25-gauge, 1½-inch needle
- 0.5% lidocaine with epinephrine
- Povidone-iodine (Betadine) or chlorhexidine (Hibiclens) prep
- Sterile draping
  - Sterile gloves and Occupational Safety and Health Administration (OSHA)–approved attire for the clinician to observe universal blood and body fluid precautions
- · Set of phlebectomy hooks
- Curved iris scissors
- Minimum of six curved micro mosquito forceps
- Four towel clamps
- Needle holder (to hold the blade at proper location to produce desired depth and length of incision [see Fig. 85-5])
- No. 11 scalpel blade (alternative, 18-gauge needle)
- 3-0 absorbable suture (e.g., Vicryl)
- 4 × 4 gauze
- Steri-Strips (plain or saturated with povidone-iodine)
- Benzoin spray
- 4-inch web roll (as an absorbent wrap over the 4 × 4 dressing)
- Nonstretch compression dressing (e.g., Comprilan, Coban)
- Class II thigh-high compression stockings
- Shower bag to cover dressing, when needed
- Written postoperative instructions
- Consent form

## ANATOMY AND PATHOLOGY OF VENOUS DISEASE

Before proper treatment options can be determined, the clinician must have a clear understanding of the patient's underlying anatomy and disease process. The clinician should also have undertaken some advanced study of the overall anatomy and diseases of the lower extremity venous system; some specialized training should have been obtained before performing AP. This section serves only as a brief overview and is far from comprehensive. (The reader is again referred to Chapter 86, Endovenous Vein Ablation, Chapter 88,

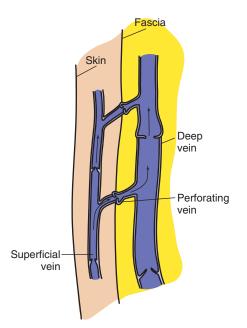

Noninvasive Venous and Arterial Studies of the Lower Extremities, and Chapter 92, Sclerotherapy.)

There are primarily three venous systems in the leg: the superficial venous system lies above the deep fascia, the deep venous system lies under the deep fascia, and the perforator vein system connects the superficial with the deep systems (Fig. 85-1). The muscular pump of the leg produces a distal-to-proximal compression to facilitate blood flow back to the cardiopulmonary system. If the valvular system is intact, normal veins allow only unidirectional flow.

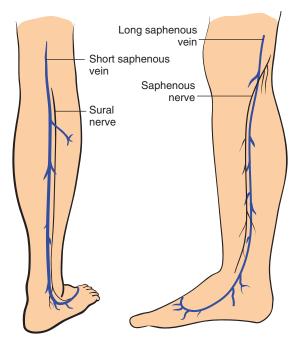

The superficial venous system consists of a network of veins that feed two primary vessels, the great saphenous vein and the short saphenous vein. The great saphenous vein terminates at the saphenofemoral junction after it has coursed proximally from the dorsal arch vein of the foot and medially along the medial leg and thigh. The short saphenous vein also begins with the dorsal arch vein but travels behind the lateral malleolus and along the lateral leg. After reaching the popliteal fossa, the short saphenous vein empties into the popliteal vein of the deep venous system at the saphenopopliteal junction. It should be noted that the location of this junction is variable (see Chapter 92, Sclerotherapy, Figs. 92-2 and 92-3).

Perforator veins allow blood to flow from the superficial to the deep system. By doing so, more than 90% of blood flows through the deep venous system on its way back to the heart. The importance of competent venous valves for enforcing unidirectional flow in such a low-pressure system is often unappreciated. Once venous reflux occurs through incompetent valves, normal blood flow is altered, intraluminal pressure increases, and the disease process worsens. The increased flow and pressure to the superficial system leads to dilated vessels and the development of varicosities. As chronic venous insufficiency develops, approximately one third of patients also develop problems with superficial thrombophlebitis, dermatitis, lipodermatosclerosis, or ulceration.

It is also important for the phlebologist to have a clear understanding of the sensory nerves and lymphatic vessels of the leg. Both of these systems lie close to the superficial veins. Consequently, complications can develop from damage to these structures. The most frequent nerve damage occurs to the saphenous or the sural nerve or their branches. The saphenous nerve is most vulnerable at the location where it lies along the distal portion of the great saphenous vein near the dorsal foot veins. The sural nerve is vulnerable along its entire course as it runs beside the short saphenous vein

**Figure 85-1** Venous compartments of the leg consist of the superficial venous system, the deep venous system, and the perforator vein system.

**Figure 85-2** Important sensory nerves and their location relative to vessels of the leg.

(Fig. 85-2). Damage to the lymphatic vessels most commonly occurs below the medial knee in the anterior tibial region near Boyd's perforators.

#### PREPROCEDURE PATIENT PREPARATION

An accurate patient history and physical examination will allow the clinician to formulate a better diagnosis and treatment plan, one that is best suited for the patient's needs. The examination must also exclude any potential contraindications. Additional studies, such as an electrocardiogram, complete blood count, bleeding studies, and serum electrolytes, glucose, urea nitrogen, and creatinine levels, may be required. Figure 85-3 shows a general history form with a focus on venous-related symptoms or diseases.

The venous examination should result in an accurate map of the veins of the lower extremities. The clinician should also note if chronic venous changes are present. Dermatitis, edema, corona phlebectatica, and lipodermatosclerosis or ulcerative disease may raise a suspicion for deep venous disease or long-standing chronic venous insufficiency.

The handheld Doppler is often referred to as the "phlebologist's stethoscope." It is an invaluable instrument for examining the patient for venous reflux. The Doppler examination is performed with the patient in the standing position, bearing his or her weight on the opposite leg. The Doppler probe is placed at a 45-degree angle over the vein to be examined. Compression of the calf muscle distal to the probe induces blood flow in a proximal direction. In a diseased vein, reflux is heard as a loud rumbling sound after the sudden release of compression of the calf muscle. A normal vein has only a monophasic (unidirectional) signal. By performing this simple maneuver, the examiner can locate the highest, most proximal source of reflux. (See also Chapter 88, Noninvasive Venous and Arterial Studies of the Lower Extremities.)

Duplex ultrasonographic examination provides information useful for producing an even better venous map. The examination is typically performed with a 7.5- to 13-MHz linear probe and the patient in a standing position. Areas of venous dilation or large perforators can reveal sources of proximal venous reflux. The deep venous system can also be visualized to assess for thrombus or

incompetence. Areas of reflux in the superficial system, which may be difficult to visualize or palpate, can be studied easily. Duplex scanning also provides a hard copy (image and often a blood velocity graph) for documentation of the venous disease before and after treatment

Many phlebologists evaluate the leg function with an additional test, photoplethysmography. This is most helpful to document normal or correctable deep venous function in those patients with evidence of stasis changes (see Chapter 92, Sclerotherapy).

Once a thorough understanding of the underlying disease process is obtained, an accurate treatment plan can be formulated. It needs to be emphasized that the highest, most proximal point of reflux must be corrected. This often requires a procedure in addition to AP. Ablation of the saphenous vein, ultrasonography-guided sclerotherapy (often referred to as "chemical ablation"), or a partial stripping or ligation of the great or short saphenous vein may be needed in conjunction with AP. If the venous incompetence cannot be treated with these techniques or the clinician does not have the training or skills to perform them, the clinician may choose to consult another surgeon. This consultation helps to ensure a lower recurrence rate and better relief of the symptoms from venous insufficiency.

See the sample patient education form available online at www. expertconsult.com.

#### **TECHNIQUE**

- 1. On the night before surgery the patient should shave his or her legs carefully, minimizing any nicking. Instead of shaving, patients (especially men) may prefer to use "Magic Hair Removal" or a depilatory.
- 2. Preoperative pictures are highly recommended.
- 3. Just before surgery, have the patient stand for venous marking with a surgical marking pen. Proper lighting in a warm room, and having the patient stand for a period of time, will maximize venous dilation and visibility. In turn, this will improve the clinician's ability to mark the veins. Some clinicians mark the most superficial and easily palpable portion of the vein with a crosshatch. A vein transilluminator (Veinlite) is helpful for ensuring accurate marking.
- 4. Once the visible veins have been marked, use a focused Duplex examination to locate and mark the perforator veins (and any large branches along the vein) that are to be excised (Fig. 85-4).
- Place the patient in 10 to 15 degrees of Trendelenburg to empty the veins during surgery. The foot can be propped on a pillow or cushion.
- Prepare the area with a 5-minute povidone-iodine (Betadine) or chlorhexidine (Hibiclens) scrub and then apply sterile drapes to the area.
- 7. Inject 0.5% lidocaine with epinephrine on each side of the marked veins using a 25-gauge, 1½-inch needle.
  - **NOTE:** Many clinicians use a tumescent technique, originally developed for use in liposuction surgery. Larger amounts of dilute local anesthetic (0.2% lidocaine with a 1:500,000 concentration of epinephrine) are instilled perivascularly with a 22-gauge spinal needle. These clinicians believe that instilling larger volumes into the perivascular space provides additional local compression and further minimizes risk of bleeding after the procedure.
- 8. Starting proximally, make a small 2- to 3-mm vertical incision over or adjacent to the marked vein. A no. 11 scalpel blade or an 18-gauge needle may be used for the incision. A no. 11 blade can be held in a needle holder at the proper location to produce the desired depth and length of the incision (Fig. 85-5).
- 9. Gently insert a phlebectomy hook through the incision (Fig. 85-6). It may be necessary to break up adhesions and fibrous

- attachments to the vein, before extraction, by undermining the vein and surrounding skin and subcutaneous tissue with the stem of the phlebectomy hook. However, be careful not to damage any nearby structures such as nerves or lymphatics.
- 10. Hook the vein with a gentle rotation and retraction technique. When the vein is pulled through the incision, it will be identified by its distinguishing pearly white appearance (Fig. 85-7).
- 11. The vein is grasped with a set of fine curved mosquito hemostats. As the vein is exteriorized, the tension on the vein will produce a palpable cord under the skin. The next incision is made at the distal point of the palpable cord, or the next crosshatch.
- 12. The most proximal end of the vein being excised is tied off with absorbable suture (e.g., 3-0 Vicryl). The author also chooses to tie off as many perforators as possible, and these were easily located and marked with Duplex before surgery. Many phlebologists choose to simply tear the vein loose from the perforator and have an assistant apply constant pressure to the area for 5 to 10 minutes.
- 13. The vein is sequentially pulled through successive distal incisions until it is totally excised. When removed in pieces, these can be laid out along the course to ensure total removal of the vein (Fig. 85-8).
- 14. With extensive varicosities, the surgeon may choose to perform the AP in stages, separated by 7 to 14 days between each surgery. The procedure, when performed in stages, typically begins on the distal part of the limb. With experience it will take the surgeon less time to remove the same length of vein. Several hours should be allowed for each surgery, and only one leg should be done at a time.
- Clean the limb with sterile water and pat dry. Benzoin spray is used to increase the adhesion of the Steri-Strips applied over the incisions.
- Apply gauze or an absorbent padding along the course of the excised vein.
- 17. Wrap the leg in a distal-to-proximal direction with a nonstretch compression bandage (e.g., Comprilan, Coban).
- 18. Place a thigh-high, class II compression stocking over the dressing.

#### **COMMON ERRORS**

- Not making sure the highest, most proximal point of reflux is corrected
- Administration of the anesthetic too deep into the tissue
- Making incisions too large, resulting in excessive scaring
- Overzealous hook movement and pulling, resulting in superficial nerve damage or skin damage
- Poor approximation of incisions
- Not providing sufficient padding at pressure points or leaving creases under the compression dressing
- Not ensuring and stressing the importance of walking regularly after the procedure

#### **COMPLICATIONS**

Box 85-1 shows a list of complications seen in a review of the literature done by Ramelet (1997). The rate of transient, patient-perceived complications might be as high as 5% to 10%, including such things as skin blisters, hyperpigmentation, and contact dermatitis (Table 85-1). True complications that require professional attention or that have long-term sequelae are quite rare.

Complications can be divided into cutaneous, vascular, and neurologic. Most *cutaneous complications* can be avoided with the proper use and application of the postoperative dressing. The size and type of vessels operated on, the anatomic location of the surgery, and the individual patient's history of previous sclerotherapy, phlebitis,

or lipodermatosclerosis will all affect the likelihood of a vascular complication. Many of the *vascular complications* are avoidable by applying adequate compression and stressing the importance of postoperative ambulation. *Neurologic complications* can occur from the local anesthetic, directly from the phlebectomy, or from the postoperative dressing. The most problematic nerve injury is damage to the sural nerve; this must be avoided by dealing carefully with the short saphenous vein. Damage to sensory nerves can often be

avoided because the patient will usually complain of pain if the surgeon is too close to the nerve; this awareness allows the surgeon to avoid damaging or destroying the nerve. Excessive compression to the dorsal foot can induce a painful tarsal syndrome.

The primary care clinician does not require special training to handle the complications that occur with AP. Emphasis must be placed, however, on adequate training to perform AP and on the proper understanding of the underlying pathophysiologic process.

## POSTPROCEDURE MANAGEMENT AND PATIENT EDUCATION

Written and oral postoperative instructions should be provided to the patient (see the sample patient education form available online at www.expertconsult.com). All patients should be encouraged to walk approximately one half mile immediately after surgery, then 1 to 3 miles per day for the next 2 weeks. They should start taking one aspirin daily for 2 weeks, starting 12 to 16 hours after surgery.

Strenuous workouts, heavy lifting, and standing for long periods of time should be avoided for 2 weeks. Over-the-counter ibuprofen should be sufficient for any discomfort that may occur after surgery. The dressing should remain in place and be kept dry until the follow-up appointment 1 week later. At that time, the dressing will be removed and the incisions inspected. The compression stocking alone is worn during the day for an additional week. The Steri-Strips are removed 2 weeks after surgery, and then any further surgeries or required therapy can be scheduled.

## ENDOVENOUS VEIN ABLATION

Jerry Ninia

Primary venous insufficiency is characterized by the development of varicose veins of the lower extremities. The great saphenous vein (GSV) is the largest and longest vein of the superficial venous system, and reflux in the GSV is often associated with the development of large superficial varices. In addition to cosmetic issues and symptoms of leg pain and fatigue, varicose veins can give rise to ambulatory venous hypertension with its associated skin changes and ulceration. In fact, up to 80% of leg ulcers are due to venous disease. If incompetence of the saphenofemoral junction (SFJ) or a perforator vein is detected, treatment is medically indicated. In addition, reflux in other veins such as the small saphenous vein (SSV), anterior accessory saphenous vein, and vein of Giacomini may contribute to the development of varicose veins. This chapter describes ultrasonography-guided percutaneous techniques for treating patients with varicose veins who are ambulatory and whose sonographic findings include the documentation of reflux.

Knowledge of lower extremity duplex ultrasonography is an absolute necessity for the performance of these procedures. The venous anatomy is described in Chapter 92, Sclerotherapy. Patients need to be evaluated before surgery with ultrasonographic mapping and marking, during surgery with guiding and checking, and after surgery for response to treatment. *Mapping* refers to diagramming the findings on the patient's chart. *Marking* pertains to outlining vein findings on the patient's skin. Intraoperative *guiding and checking* refers to proper performance of the procedure and proper instrumentation and application of tumescent anesthesia. Response to treatment is assessed at 1 week, 1 month, and longer intervals as needed to determine the effectiveness of the procedure.

#### **ENDOVENOUS CHEMICAL ABLATION**

Also see Chapter 92, Sclerotherapy, which discusses many of the concepts and the anatomy involved in treating venous diseases.

Commonly referred to as "ultrasonography-guided sclerotherapy," endovenous chemical ablation (ECA) involves injecting a sclerosing solution under ultrasonographic guidance directly into the lumen of the vein being treated. Even if the vein has significant tortuosity the sclerosant (liquid or foam) will distribute itself within the vein lumen. An example is the use of ECA in the treatment of patients with groin neovascularization—a phenomenon seen in patients who have previously undergone surgical vein stripping. As such, ECA is especially helpful in treating these patients with postsurgical recurrences and an anatomically variable SSV with its associated tortuous tributaries. Equipment needed is very similar to that used for basic injection-compression sclerotherapy, with the addition of a 7.5- to 15-MHz linear-array ultrasound transducer. Ultrasonography provides real-time feedback to confirm intraluminal placement of the needle tip or catheter, intraluminal injection without extravasation, and attainment of the treatment end point (i.e., vasospasm; Fig. 86-1). Vasospasm is an indicator of the immediate efficacy of the foam injection; however, the final therapeutic effects of foam sclerotherapy should be evaluated clinically according to symptoms and follow-up duplex ultrasonography. Tumescent

anesthesia is not required. Graduated class II (30 to 40 mm Hg) compression stockings need to be worn *continuously* for 24 to 36 hours, then during the daytime for 6 days postinjection.

The direct needle injection technique involves ultrasonographic visualization of the vein in a longitudinal plane (Fig. 86-2). A 21- to 25-gauge, 1- to 1½-inch needle is inserted obliquely into the lumen of the vessel with the bevel directed up. Slow aspiration is performed to verify correct needle placement. A small amount (1 to 2 mL) of sclerosant foam or liquid (1% to 3% sodium tetradecyl sulfate [STS]) is injected slowly; a "snowstorm" sonographic pattern is appreciated on injection (Fig. 86-3).

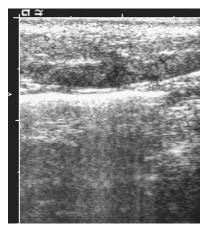

#### Foam Sclerotherapy

Although liquid sclerosants can be used, for larger veins the effect of sclerotherapy is enhanced by creating a sclerosant foam. Foam is created using the Tessari technique (Fig. 86-4). The Tessari technique involves using one syringe with liquid detergent sclerosant (e.g., STS 0.1% to 3%, polidocanol 1% to 2%, and others) and another syringe with air. The ratio of air to sclerosant is 4:1. The syringes are connected by a two- or three-way stopcock. By forcing the air and fluid back and forth numerous times, foam is created. The sclerosant is supposedly concentrated on the bubbles and thus has greater potency, leading to more efficacious treatment. The foam reconstitutes into liquid very quickly, within a matter of minutes, so it needs to be injected rather quickly. Although not mandatory, using rubber-free and Silicone-free syringes (e.g., B. Braun Injekt) prolongs the foam state. This technique is simple and economical and produces good-quality foam. Ultrasonography will demonstrate more of a "snowstorm" pattern when foam is injected. Amounts and concentrations depend on the size and number of veins injected. Although foam can be used for telangiectases, complications may be more frequent and hence the technique is more commonly reserved for larger veins.

Whether foam or liquid is used, injections are administered with the patient supine, starting in the distal leg and progressing proximally to the point of reflux in order to minimize the volume of sclerosant and number of injections. Alternatively, injections can be administered starting 8 to 10 cm distal to the point of reflux, then proceeding from proximal to distal as previously injected segments undergo vasospasm. If 3% liquid STS is used, the maximum amount of solution during a treatment session is 10 mL. If foam is used, the volume limit is 10 mL of foam sclerosant as well, regardless of the concentration of the liquid detergent sclerosant used to create the foam (Breu and colleagues, 2008).

#### **Needle versus Catheter Infusion**

The *syringe-and-needle technique* is technically less difficult than the *catheter infusion technique*; however, it has a narrower margin of safety. This is due to the need for multiple injections and the potential for vein laceration and subsequent sclerosant extravasation.

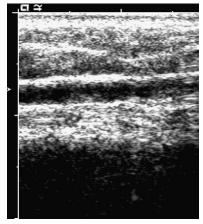

**Figure 86-1** Vasospasm end point. (Courtesy of Nick Morrison, Scottsdale, Ariz.)

The catheter infusion technique involves the introduction of a peripherally inserted central catheter line or a 2.5-inch, 18-gauge intravenous catheter fully inserted directly into the lumen of the vein. The catheter tip is initially located 8 to 10 cm distal to the point of reflux (Fig. 86-5). The sclerosant is injected slowly as the catheter is withdrawn. Subsequent percutaneous catheter placements are made distally and injections are directed cephalad as previously injected segments undergo vasospasm. Often, incompetent perforator veins do not require direct injection because they respond to treatment of the overlying superficial vein.

**NOTE:** When using the catheter infusion method, venipuncture sites are placed sequentially moving distally, with injections of the foam directed proximally (cephalad). When using the syringe-and-needle technique, injections are made from proximal to distal, with injections also directed cephalad.

Complications of ECA include those that may occur with standard injection—compression sclerotherapy. Deep venous thrombosis (extremely rare—incidence is between 0% to 5.7%) may occur if sclerosant finds its way into the deep venous system, especially in cases of inadequate post-ECA compression and lack of ambulation. Other side effects reported after ECA include transient visual disturbances, with no long-term visual or neurologic sequelae reported to date. Intra-arterial injection—the most feared complication of sclerotherapy—has been reported more frequently in association with ECA. This can cause severe skin necrosis; limb amputations have been reported as well. Therefore, performance of ECA must

**Figure 86-2 Vein imaged longitudinally.** (Courtesy of Nick Morrison, Scottsdale, Ariz.)

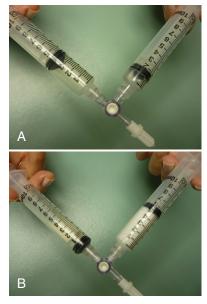

**Figure 86-3** "Snowstorm" pattern (arrow) after injection. (Courtesy of John Mauriello, MD, Bradenton, Fla.)

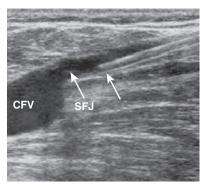

not be undertaken lightly. Detailed knowledge of the vascular sonographic anatomy is essential to perform ECA properly, safely, and effectively.

## ENDOVENOUS RADIOFREQUENCY AND LASER ABLATION

Over the past several years, in addition to ECA, there has been the introduction of newer procedures in the treatment of chronic venous insufficiency. *Endovenous radiofrequency ablation* (RFA) and *endovenous laser ablation* (ELA) have emerged as less invasive and more effective alternatives to vein stripping. Performed in an office setting using *tumescent anesthesia*, these procedures can often be completed in under 1 hour. Procedure times depend on how long it takes to access the vein percutaneously, the length of the vein, and whether it is necessary to perform any ancillary procedures such as sclerotherapy or ambulatory phlebectomy. Graduated compression stockings are required post-treatment, as they are for ECA.

**Figure 86-4** The Tessari technique. **A**, A 4: I ratio of air to liquid sclerosant. **B**, The product after foam is created.

**Figure 86-5** Catheter tip (arrow) I cm below the saphenofemoral junction (SFJ).

With RFA, radiofrequency energy is delivered to the vein lumen to heat, shrink, and occlude refluxing saphenous veins. Occlusion results from the contraction of collagen in the vein wall. VNUS ClosureFAST (VNUS Medical Technologies, San Jose, Calif) uses a specially designed catheter to treat 7-cm segments of the vein while maintaining intraluminal temperature at 85° C to 90° C (Fig. 86-6). A 35-cm-long vein can be treated in 2 minutes. With ELA, laser energy of varying wavelengths is delivered to the vein lumen. Examples of wavelengths used for ELA include 810 nm (AngioDynamics, Latham, NY), 980 nm (Biolitec, East Long Meadow, Mass, and Angio Dynamics, Latham, NY), and 1320 nm (CoolTouch, Roseville, Calif). Laser treatment generates steam by heating blood inside the vein, producing fibrosis and subsequent occlusion of the vein. Deoxygenated hemoglobin is the main chromophore of the 810- and 980-nm lasers, whereas the energy of the 1320-nm laser is directed toward water in the vein wall. If treatment failure (recanalization) occurs (10%), it usually develops within the first year. If the vein is closed at 1-year follow-up, it is unlikely to recanalize.

#### **Indications**

The following are indications for RFA and ELA:

- Fully ambulatory patient without any contraindications
- Bulging varicose veins with or without symptoms (e.g., leg heaviness, throbbing, aching)

**NOTE:** In some female patients, symptoms may occur only premenstrually (see Ninia, 2008).

Figure 86-6 Catheter. (Courtesy of Covidien, Mansfield, Mass.)

- Bulging varicose veins with or without dermatologic signs of chronic venous insufficiency (e.g., edema, hyperpigmentation, lipodermatosclerosis, ulceration)
- Duplex ultrasonographic findings consistent with incompetence of the GSV or SSV
- Minimal tortuosity of the GSV or SSV to permit catheter placement

#### **Contraindications**

- RFA cannot be used in patients with pacemakers.
- Contraindications to treatment with all methods include inability to ambulate, active superficial or deep venous thrombosis, hypoplastic deep veins, poor health, and pregnancy.

#### **Equipment and Supplies**

- Basic equipment for ELA and RFA (Total Vein Solutions, Houston, Tex; Vascular Solutions, Minneapolis, Minn)
- Duplex ultrasonography equipment, available as portable or stationary units (Fig. 86-7)
- Povidone–iodine and sterile drapes
- Sterile gloves
- Drapes
- Ultrasound probe cover
- 1% lidocaine without epinephrine, 5-mL syringe, and 30-gauge needle for local anesthesia before inserting the angiocatheter
- No. 11 blade
- 18-gauge angiocatheter
- Luer-Lok syringes
- Class II graduated compression stockings
- J-wire (guidewire)
- Sheath and vein dilator
- Micropuncture kits, available for veins less than 3 mm in diameter

**Figure 86-7** Duplex ultrasonography equipment is available as portable (**A**) or stationary (**B**) units. (Courtesy of Sonosite, Bothell, Mass.)

- Protective eyewear for use during laser procedures
- Skin marking pen
- Fluid for tumescent anesthesia. Various preparations of tumescent solutions have been used, with studies showing the maximum safe dose of lidocaine to be 35 mg/kg. In general, a dilute solution of lidocaine can be prepared by taking a 250-mL bag of 0.9% normal saline, removing 15 mL, and replacing it with an equal amount (15 mL) of 1% lidocaine. A small amount (5 mL) of sodium bicarbonate can be added as a buffer to decrease the stinging sensation.

**NOTE:** Supplies are available commercially from various sources (e.g., Vein Solutions, Total Vascular Solutions, Cook Medical [Bloomington, Ind]). The endolaser and radiofrequency companies preassemble kits that contain necessary supplies.

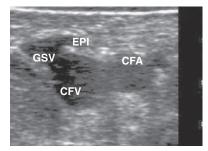

#### **Preoperative Patient Education**

See patient education forms online at www.expertconsult.com.

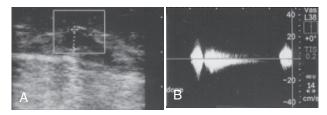

#### **Procedure**

A preoperative evaluation is carried out, usually on a date before that of the procedure, and begins with a directed history and physical examination with an emphasis on the lower extremities of patients with varicose veins. Type and duration of symptoms along with any improvement with support stockings should be documented. Skin changes related to ambulatory venous hypertension, such as edema, hyperpigmentation, corona phlebectasia, lipodermatosclerosis, atrophie blanche, and ulceration, are best documented with photography.

- 1. Patients are premedicated orally with 0.5 mg of the anxiolytic alprazolam 30 minutes before the procedure.
- 2. The ultrasonographic examination is performed with the patient standing and the weight shifted onto the opposite leg (see Chapter 88, Noninvasive Venous and Arterial Studies of the Lower Extremities). For the GSV, start at the groin and work caudad along the medial thigh. The GSV is identified in its characteristic location at the SFJ and then within the fascial sheath (Fig. 86-8). Its course is marked on the skin. Vein diameter should be measured along with documentation of reflux by Doppler analysis (Fig. 86-9). Reflux is demonstrated by an audible retrograde flow of greater than 0.5 to 1 second while manually compressing and releasing the calf muscles. Significant reflux of 2 seconds or more is often associated with skin changes characteristic of venous insufficiency. Documentation of this finding is necessary to secure reimbursement as a medically necessary procedure.
- After venous duplex mapping and marking, a percutaneous entry point is chosen.

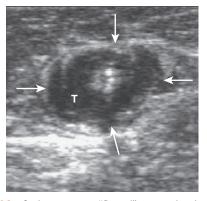

**Figure 86-8** Sonographic appearance of great saphenous vein (GSV) joining common femoral vein (CFV) at the saphenofemoral junction. EPI, superficial epigastric artery; CFA, common femoral artery.

**Figure 86-9 A,** Great saphenous vein (GSV) within the fascial sheath. This vessel was measured at midthigh and noted to be approximately 0.57 cm in diameter. **B,** Quantification of reflux of the GSV in (**A**). After manual compression of the calf muscles, reflux lasts approximately 2 seconds.

- 4. The *leg is prepared and draped* in sterile fashion using povidone—iodine, and the access site is visualized longitudinally with ultrasonography.
- 5. A 1% lidocaine wheal is raised at the access site.
- 6. An 18-gauge, 2-inch angiocatheter is inserted into the vein (Terumo, Somerset, NJ). A 0.035-inch-diameter J-wire (guidewire) is placed through the angiocatheter and directed toward the SFJ. The angiocatheter is removed. The percutaneous entry site is slightly widened and a 5-Fr sheath with a dilator is placed over the guidewire. The sheath is positioned 1 cm below the SFJ. This serves to preserve the superficial epigastric vein. A competent superficial epigastric vein preserves venous drainage of the anterior abdominal wall and prevents the phenomenon of neovascularization—the condition associated with vein recurrences after surgical ligation and stripping. The J-wire and dilator are then removed. Venous return is confirmed by aspirating the syringe attached to the sheath.
- 7. At this point, either an RFA or an ELA catheter is introduced into the sheath. In the case of laser, the aiming beam of the 600-µm laser fiber tip is transilluminated through the skin. If the aiming beam is not seen, it suggests that the laser fiber tip is incorrectly placed in the deep venous system. In this circumstance, the laser fiber and sheath need to be withdrawn until the aiming beam is visualized.
- 8. Tumescent anesthesia is administered after the laser fiber or the RFA catheter has been inserted. It is injected manually or with the use of a mechanical pump (Klein pump, HK Surgical, San Clemente, Calif) perivascularly into the saphenous sheath with ultrasonographic guidance, and the GSV is then "floated" in the anesthetic fluid (Fig. 86-10). In addition to providing anesthesia, this compresses the diameter of the GSV and causes the vein to spasm. The fluid surrounding the vein also provides for a "heat sink" to prevent injury to adjacent tissue.

**Figure 86-10** Saphenous vein "floated" in its sheath (arrows) after perivascular administration of tumescent anesthetic. The "T" represents the tumescent liquid surrounding the vein. Note how, in transverse view, the vein spasms around the echogenic laser fiber after the tumescent fluid is administered. This liquid now serves as a heat sink to absorb heat energy from the laser.

9. Delivery of RF or laser energy is now administered. For RF, using a "segmental heating" approach, the ClosureFAST catheter is positioned as described.. The exposed 7-cm heating element portion is activated with RF energy for a 20-second heating cycle. When the cycle is complete, energy delivery is automatically terminated by the generator. The catheter is then repositioned to the next treatment zone as indicated by the markings on the catheter. Spaced at increments of 6.5 cm, the catheter shaft allows for a 0.5-cm overlap between each treated segment to ensure complete treatment along the length of the vein. In addition to speed, an advantage of RFA over ELA is that the energy delivered is controlled by the temperature sensor on the catheter. This minimizes the risk of vein perforation and associated postoperative pain and bruising.

In general, for all laser units, a minimum of 70 J/cm is needed to successfully occlude the vein. This can be accomplished by delivering 14 W of power and using a fiber withdrawal rate of 2 mm/sec, the latter of which is accomplished simply and accurately by using the 10-cm markings along the sheath in conjunction with the time display in seconds on the individual laser unit

 A class II (30 to 40 mm Hg) thigh-high, open-toe graduated compression stocking is immediately applied to the treated leg.

#### **Common Errors**

- If the vein spasms, application of a small amount of 2% nitroprusside may help correct the vasospasm. Alternatively, the patient may ambulate for 10 minutes and venepuncture may be reattempted.
- The room temperature is too cold.
- The patient is in the wrong position (reverse Trendelenburg is correct).
- Not attending to the needs of a nervous patient. Anxiolytics (lorazepam 0.5 to 1 mg) work well. "Vocal anesthesia" and speaking to the patient during the procedure may also help allay anxiety.

#### **Postprocedure Patient Care and Education**

See the patient education forms online at www.expertconsult.com. Patients are encouraged to ambulate and resume their normal activities.

- The compression hose is worn overnight and then for 6 more days while the patient is up and ambulating. The stocking may be removed at bedtime and for showering.
- Ibuprofen 600 mg three times daily is prescribed for 3 days and is to be taken, then used every 6 hours as needed afterward for pain.
- Physical examination and ultrasonographic follow-up are performed 3 to 7 days post-treatment (Fig. 86-11).

The treated vein wall will be thickened and fibrotic. Adequate flow in the deep venous system should be noted (Fig. 86-12). Although a resolution of symptoms and an improved cosmetic appearance are often noted within 1 month of treatment, most patients will need additional therapy in the form of sclerotherapy or ambulatory phlebectomy of residual varices to attain maximum results. Telangiectases will need to be treated separately as well. Some operators perform these procedures at the time of the endovenous ablation procedure. Others prefer to wait 1 month post-procedure to see what, if any, additional procedures need to be performed.

#### **Complications**

Significant complications of RFA and ELA are rare.

- Bruising and discomfort tend to be more common with ELA.
- Local paresthesias can occur with both modalities (<5% with</li>

**Figure 86-11** Appearance before (**A**) and after (**B**) endovenous laser ablation.

ELA and <15% with RFA) but typically resolve within 2 to 3 months. Application of adequate tumescent anesthesia by floating the vein at least 10 mm below the skin will reduce this risk.

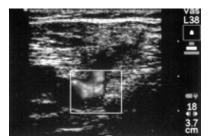

- The incidence of deep venous thrombosis is reported to be less than 1% with both modalities. This is very rare, especially when immediate ambulation and compression are used.
- Failure rates for either RFA or laser are less than 2% at 5-year follow-up.

#### **CONCLUSIONS**

Results of endovenous therapies have been very encouraging. Compared with vein stripping, these office-based procedures offer the advantages of lower procedural risks and cost. Patients are awake during the procedures and remain fully ambulatory, with no downtime afterward. Over the past several years there has been an increased understanding and interest in the management of venous disease. Over the next several years, these promising minimally invasive endovenous ablative procedures will essentially replace vein stripping.

#### **PATIENT EDUCATION GUIDES**

See sample patient education and consent forms online at www. expertconsult.com.

**Figure 86-12** Postprocedure blood flow in a common femoral vein (CFV). Because this is a deep vein, one would want to see blood flow in its lumen both before and after the procedure. Compromised blood flow in the CFV postprocedure raises concern over an iatrogenic deep venous thrombosis.

#### **CPT/BILLING CODES**

36475	Endovenous ablation therapy of the incompetent vein, ex-
	tremity, inclusive of all imaging guidance and monitor-
	ing, percutaneous, radiofrequency; first vein treated

36476 Second and subsequent veins treated in a single extremity, each through separate access sites

36478 Endovenous laser ablation therapy of incompetent vein, extremity, inclusive of all imaging guidance and monitoring, percutaneous, laser; first vein treated

36479 Second and subsequent veins treated in a single extremity, each through separate access sites

## AMBULATORY ELECTROCARDIOGRAPHY: HOLTER AND EVENT MONITORING

David Flinders • Scott Akin

Norman Holter developed ambulatory electrocardiography in the form of Holter monitoring in the early 1960s. The first device weighed about 85 pounds, and was worn as a backpack. As the technology, availability, and convenience of equipment have improved, use of ambulatory electrocardiography (AECG) has increased. Although in the past Holter recordings were primarily requested, provided, and interpreted by cardiologists, this procedure, as well as other forms of AECG, have become increasingly popular among primary care clinicians. As our population ages, the prevalence of arrhythmias will increase, along with the prevalence of cardiovascular disease. Routine use of AECG generally involves evaluation of patients who report symptoms possibly related to cardiac arrhythmias, such as unexplained palpitations, unexplained syncope, presyncope, or episodic dizziness. More advanced (and in some cases more controversial) uses of AECG include arrhythmia detection in asymptomatic patients with cardiac risk factors, ST segment monitoring for silent myocardial ischemia in the patient with coronary artery disease (CAD), assessment of antiarrhythmic drug therapy, and assessment of pacemaker/implantable cardioverterdefibrillators (ICD) function.

As primary care clinicians have increased their competence in use of AECG devices, they have become more comfortable providing access to them in their offices. Benefits include more readily, and perhaps more rapidly, available data for their patients. These data allow for more complete and definitive care for many patients. AECG is attractive because it requires little of the clinician's time to interpret the results and is therefore a time-efficient, incomegenerating test. With more widespread use, the cost of equipment has also decreased. However, acquisition of an office monitoring system is not a decision to be taken lightly. Although it is relatively easy to interpret the results, it is considerably more difficult to apply them clinically. The clinician must have a clear interest in cardiac arrhythmias and be willing to invest the time needed to learn the system. The clinician must also make the commitment to promptly interpret the results of all tests performed. Realistically, with training and a modicum of practice, clinicians can interpret and dictate the results of most Holter reports within 5 to 15 minutes. Interpretation of event monitoring usually takes even less time. However, despite being more readily available, ambulatory monitoring should not be considered a routine procedure. From the patient's and insurer's perspective, it is expensive and time consuming. It should be reserved for specific indications. This chapter outlines the different types of AECG, their indications, and the techniques necessary for use, and provides a foundation for basic AECG interpretation.

## OVERVIEW AND COMPARISON OF AVAILABLE METHODS OF EVALUATION AND ARRHYTHMIA MONITORING

#### 12-Lead ECG and Rhythm Strip

- Only monitors cardiac rhythm for a short period. Therefore, unless the patient is symptomatic at time of ECG, it is difficult to correlate clinically.
- Can diagnose certain conditions associated with worrisome arrhythmias (hypertrophic cardiomyopathy, Brugada syndrome, long QT syndrome, etc.).
- Inexpensive and readily available.

## 24-Hour Holter Monitor (Often Extended to 48 Hours)

- Standard monitoring modality for arrhythmias that occur frequently (i.e., several times daily).
- Patient wears two to three electrodes on the chest with leads attached that communicate continuously with a data-collecting device worn on the patient's belt.
- Patient completes a diary that enables a correlation of symptoms with the timing of arrhythmias.
- Because the recording period is short (24 to 48 hours), it only detects arrhythmias that are responsible for symptoms approximately 10% of the time. It may miss infrequent but potentially dangerous arrhythmias.
- Can identify subjects with worrisome arrhythmias (as well as quantify the frequency, duration, etc.) and silent ischemia. However, the interpreter must be aware of the tremendous spontaneous variability in frequency not only of ectopy, but also of ST segment changes that may or may not indicate ischemia (see later discussion).
- Moderately expensive (\$250 to \$500 per test in most institutions).

#### **Postevent Recorders**

- The device is kept by the patient at all times for up to several weeks. While experiencing symptoms, the patient places the device on the chest and activates the device (the device does not record the ECG until the patient activates it). The patient can then transmit the recording over the telephone.
- The patient keeps the device until several recordings have been made, or for an agreed-upon time frame (usually between 2 to 6 weeks).

- The patient must be aware of arrhythmias when they occur and must maintain consciousness long enough to activate the device.
- Short-lived arrhythmias, and those preceding activation of the device, may be missed.
- Some newer devices are credit card size—small enough to carry in a wallet or to be worn as a necklace or wristwatch.
- Use is not recommended in the setting of arrhythmias that may cause serious symptoms such as syncope.
- Compliance can be problematic because of waning patient motivation without recurrent symptoms or patient error in correctly activating the device.
- Cost is more expensive than Holter monitoring.

## External Pre-Event Recorders ("Loop Recorders")

- The patient wears a recording device and electrodes (that are changed by the patient every several days and removed for bathing), usually over the period of a month.
- The standard device continuously records 5 to 10 minutes of ECG data. When the device is activated, the preceding data are captured or "frozen" and additional data are saved for a few minutes following activation at the time of an event. The data can then be transmitted over the telephone to a center for analysis. If the button is not pushed, the ECG loop continuously replaces the old data. Technicians may be on call 24 hours a day to interpret the data when transmitted. If necessary, they can coordinate a trip to the emergency department.
- The device can be programmed to detect asymptomatic arrhythmias and alert the patient to transmit data for evaluation.
- It is the recommended initial monitoring modality for patients with syncope because the activation button can be pressed once consciousness has been regained.
- It is the recommended initial monitoring modality in the workup of most patients with palpitations for which AECG monitoring is deemed appropriate.
- Compliance can be problematic (similar to postevent recorders), and in addition some patients report problems with electrode attachment and skin irritation.
- Cost is more expensive than Holter monitoring.

#### **Implantable Loop Recorders**

- For extremely infrequent arrhythmias, a device the size of a pack of gum is implanted subcutaneously in the chest under local anesthesia and is left in place for up to 24 months.
- Like other loop recorders it stores ECG data, which can be telephonically transmitted. The device can be programmed to store 1 minute of data prior to and 1 minute of data after automatic activation for a total of approximately 20 events. The device can also be activated externally and programmed to record up to 8 minutes of preactivation data and 2 minutes of postactivation data.
- It can be programmed to detect bradyarrythmias or tachyarrhythmias on a prespecified basis.
- This device is generally used in the patient who has undergone previous noninvasive testing that was nondiagnostic but who continues to have infrequent symptoms.
- This method is not a good choice for high-risk patients (those
  with prior myocardial infarction [MI] or conduction abnormalities on ECG) in whom other testing, such as tilt-table or electrophysiologic testing, may make a diagnosis earlier and thus allow
  for earlier treatment.
- Cost is more expensive than pre-event external loop recorders.

#### **Electrophysiology Studies**

 Electrophysiology (EP) studies are helpful when Holter or event monitoring results are equivocal, particularly in patients with a

- low ejection fraction, documented ischemic heart disease, and a history of syncope or near syncope.
- Used in post-MI patients at high risk of a life-threatening arrhythmia.
- Can determine whether an arrhythmia is inducible.
- Very expensive and higher risk (can provoke refractory or lifethreatening arrhythmias).

#### Signal Averaged ECG

- Signal averaged ECG (SAECG) enables detection of the substrate for potentially dangerous arrhythmias, such as ventricular tachycardia (VT), by using computed filtering and averaging of ECG complexes, which facilitates the detection of very low amplitude cardiac potentials not detectable by routine ECG.
- Generally 200 to 400 QRS complexes with the same morphology are averaged over approximately 3 to 7 minutes to record an adequate SAECG.
- Can be used to stratify risk for ventricular arrhythmias and sudden cardiac death, but only in specific settings such as post-MI, cardiomyopathies, Brugada syndrome, arrhythmogenic right ventricular dysplasia, mitral valve prolapse, ventricular aneurysms, and idiopathic VT.
- Used more widely in the past, it is now known that the positive predictive value of SAECG is poor. As a result, utility is more for its negative predictive accuracy.
- It does not quantitate the frequency of premature ventricular complexes (PVCs).
- The procedure has limited availability and is moderately expensive.

#### **Exercise ECG (Stress) Testing**

See also Chapter 93, Exercise Electrocardiography [Stress] Testing.

- Commonly used as a screening or diagnostic test for underlying cardiac ischemia or significant CAD.
- May confirm ischemia as the etiology of an arrhythmia or document its association with an arrhythmia.
- Demonstrates the effect of activity on ventricular arrhythmias.
- May detect some forms of complex ventricular ectopy not detected by Holter monitoring.
- ST segment depression in the absence of chest pain may alert the clinician to silent ischemia (but may be falsely positive).
- Not nearly as sensitive as Holter monitoring for the detection of PVCs.
- Systems are now available to check for T wave alternans, a risk factor for ventricular arrhythmias, particularly in patients with a dilated cardiomyopathy or post-MI with a decreased ejection fraction.

#### **Mobile Cardiac Outpatient Telemetry**

- Continuous ECG monitoring from three leads that communicate
  with a palm-sized monitor. On detection of arrhythmia, real-time
  data are automatically transmitted via cell phone to a remote
  monitoring center. The device generally can store data for transmission if the patient is temporarily in an area where cell phone
  transmission is unavailable.
- Allows up to 2 weeks of continuous monitoring.
- Does not require the patient to activate the device, unlike postevent and loop recorders. Technicians are on call 24 hours a day to interpret the data when transmitted. If necessary, they can coordinate a trip to the emergency department.
- May have a higher yield of arrhythmia detection or exclusion than loop recorders, though validation is still in progress.
- Expensive.

## BENEFITS AND DRAWBACKS OF AVAILABLE MONITORING METHODS

Physical examination and cardiac auscultation are unreliable for differentiating supraventricular from ventricular premature beats. The least expensive yet reliable method to document these arrhythmias is a standard 12-lead ECG with a short rhythm strip. Unfortunately, with an ECG the cardiac rhythm is monitored only for a short period. Considering that the commonly accepted definition of "frequent" ventricular ectopy is more than 10 to 30 PVCs an hour, it becomes easy to see how even "frequent" PVCs can be overlooked by this method. On the other hand, if any PVCs are noted on a short rhythm strip, it is likely that the patient has both frequent and complex ventricular ectopy. Both would probably be detected during a longer period of monitoring, such as a Holter monitor study.

In the past, Holter recordings of only a few hours' duration were used for arrhythmia detection. Although practical and economical, such brief recordings do not accurately reflect the severity of cardiac arrhythmias in many individuals. This point is best illustrated by reviewing what is known about the frequency of ventricular arrhythmias over the course of a 24-hour period. Simply stated, even with the same patient, a tremendous amount of spontaneous variability in PVC frequency exists between one Holter recording and another. Similarly, marked variability in PVC frequency also occurs in patients with chronic ventricular arrhythmias. PVC frequency varies greatly from one day to the next, between successive 8-hour monitoring periods, and even from hour to hour within a single day. Certain individuals exhibit PVCs primarily during the day; others manifest them principally at night. As might be expected, PVC frequency often varies with physical activity and emotional state. However, in many individuals, marked spontaneous variability in PVC frequency persists even when monitoring conditions are kept absolutely constant.

Because of such fluctuations in PVC frequency, a monitoring period of at least 24 hours has become the standard for adequate characterization of an arrhythmia, and thus Holter monitors are generally worn for 24 hours, though occasionally the time period is extended to 48 hours. For most individuals, 24-hour monitoring not only permits recognition of diurnal variations in arrhythmias, but it also allows detection of the maximal grade of ectopy.

The key caveat of 24-hour Holter monitoring is that no conclusions can be reached about whether a symptomatic arrhythmia exists unless symptoms occur during the 24 hours of monitoring. As noted previously, a patient may even have a malignant symptomatic ventricular arrhythmia that occurs only intermittently, sometimes as infrequently as once every few weeks. Event monitors, either in the form of a "postevent" device that necessitates patient activation or more commonly a continuously recording pre-event ("loop") device, circumvent the short time limitation of the Holter monitor, as patients use these devices for several weeks at a time.

Although many variations of event monitoring exist, patients are generally issued a device that transmits the patient's rhythm over the telephone. Usually the equipment remains with the patient for a few days or weeks. For cases of extremely infrequent arrhythmias, subcutaneously implanted units may be used for months. The principal weakness of the postevent monitor is that patients must be aware of arrhythmias when they occur, and they must maintain consciousness long enough to capture or transmit the rhythm. In the case of pre-event ("loop") recorder, the patient can activate the device after regaining consciousness, and the preceding data will be saved. Some loop recorders can be programmed to detect asymptomatic arrhythmias and alert the patient to transmit data for evaluation. These automatic detection devices typically have greater data storage capability because they may not reliably discriminate arrhythmias from artifact, potentially creating a lot of false-positive events.

In the past, most clinicians began with full 24-hour Holter monitoring and then proceeded to event monitoring only for those cases

when symptoms persisted despite negative Holter findings. However, because asymptomatic Holter results are often complicated and confusing and there is a low yield of positive findings on Holter monitoring when arrhythmias are infrequent, event monitoring is now more commonly ordered than Holter monitoring. Overall, event monitoring is at least as effective as Holter monitoring for detection of symptomatic arrhythmias; event monitoring also has the advantage of less frequently recording asymptomatic background arrhythmias (for which treatment is unnecessary). In the case of syncope and the evaluation of unexplained palpitations, the diagnostic yield of preevent loop recorders over Holter monitors has been validated, and is the preferred initial AECG modality (Kinlay and colleagues, 1996).

When Holter or event monitoring results are equivocal, EP studies may be helpful. Although EP is an invasive study, the information obtained may be critical. Patients in whom a clinically relevant arrhythmia can be induced during EP testing usually have a worse prognosis, even if asymptomatic, than patients in whom an arrhythmia cannot be induced. However, EP testing does have a small but significant false-negative rate; results in patients with nonischemic cardiomyopathy are also difficult to interpret.

SAECG is a noninvasive test that has been advocated for risk stratification in potentially lethal ventricular arrhythmias. Although its main initial use was following MI, SAECG use has expanded to include patients with cardiomyopathies, Brugada syndrome, arrhythmogenic right ventricular dysplasia, mitral valve prolapse, ventricular aneurysms, and idiopathic VT. By computer-averaging signals for several hundred recorded beats, background "noise" can be filtered out to allow detection of low-amplitude, high-frequency late potentials after the QRS. These late potentials are suggestive of areas of slower conduction that may facilitate development of ventricular reentry. Unfortunately, the positive predictive accuracy of late potentials on SAECG following MI is less than optimal, around 15% to 20% for prediction of VT or ventricular fibrillation (VF). Therefore, negative findings on this test are more useful. SAECG is of established value in the evaluation of the syncope patient, but only in the setting of ischemic heart disease, and again its value is in its negative predictive accuracy.

Exercise ECG testing (EET; see Chapter 93, Exercise Electrocardiography [Stress] Testing) is a common method for evaluating PVCs (especially in older patients or those with coronary risk factors) and other arrhythmias (especially exercise-induced arrhythmias). It serves as a convenient, noninvasive test to screen for or to diagnose underlying CAD. EET may be indicated if ischemia is diagnosed with AECG. If CAD is diagnosed, EET can also evaluate its severity and assist with its management. EET also demonstrates what effect exercise has on arrhythmias. In general, PVCs that diminish with progressively increasing activity are less worrisome and tend to be associated with a better prognosis than those brought on by low levels of exercise. Recent evidence suggests that PVCs occurring during recovery from EET are associated with increased mortality, whereas PVCs during the EET are not (Dewey and colleagues, 2008). Although not nearly as accurate as Holter monitoring for quantitative or qualitative assessment of PVCs, complex ventricular arrhythmias (including VT) and symptoms are sometimes elicited only by vigorous exercise. Chronotropic incompetence (unable to obtain heart rate >120 beats per minute) on EET may suggest sick sinus syndrome, which is best diagnosed with a Holter monitor. Holter monitoring and EET may thus be complementary procedures that provide different information, and both tests should sometimes be considered for the complete evaluation of patients with ventricular arrhythmias.

It should be emphasized that detection of PVCs per se on EET is not indicative of an ischemic response. However, PVCs are cause for more concern when they occur in association with evidence of ischemia, such as ST segment depression or substernal chest pain in patients who are likely to have CAD. Thus, it is inadvisable to allow a middle-aged individual who has coronary risk factors to exercise

in an unsupervised manner if EET produces frequent PVCs and ST segment depression or symptoms. Instead, further evaluation for CAD or ischemic or structural heart disease may be warranted.

On the other hand, many clinicians are much more comfortable allowing healthy young adults who have frequent PVCs to exercise vigorously if EET does not produce ST segment depression or if PVCs resolve with exercise. When these younger, asymptomatic, and otherwise healthy adults go out and exercise, their PVCs and symptoms will probably resolve with activity. Moreover, such individuals are much less likely to have underlying ischemic heart disease. Rare, life-threatening complex arrhythmias, seen only at peak exercise, will also be excluded with EET.

Mobile cardiac outpatient telemetry (MCOT) is an emerging technology that allows up to 2 weeks of continuous "real-time" ECG monitoring. Data collected are automatically transmitted via cell phone to a monitoring center. Benefits include less patient error because the device does not require patient activation, unlike postevent and loop recorders. A small industry-sponsored study suggested that MCOT devices may have a higher yield of arrhythmia detection or exclusion than loop recorders, although full validation is still in progress (Rothman and colleagues, 2007).

An all-too-often-ignored adjunct for monitoring is the patient's history (perception) of symptoms compatible with an arrhythmia. Although many individuals are totally unaware of their arrhythmias, others are able to sense each and every ectopic beat. For individuals with non-life-threatening arrhythmias who have this awareness—and in whom AECG has confirmed a temporal relation between symptoms and the occurrence of their arrhythmias—the *patient's account of symptoms* may serve as a fairly reliable and cost-effective adjunct for long-term monitoring (i.e., it may greatly reduce the need for [and expense of] repeated Holter recordings for judging the effect of treatment).

Consider the case of a young patient who is markedly symptomatic from extremely frequent ventricular ectopy. Baseline Holter monitoring reveals several thousand PVCs during the day of monitoring but no runs of VT and no evidence of ischemia. The echocardiogram is normal; there is no evidence of pericarditis, cardiomyopathy, or a metabolic cause for the PVCs, and the patient's diary confirms a definite temporal relationship between symptoms and periods of greatest ectopy. If treatment with a beta-blocker (or a reduction in stimulants such as caffeine) leads to complete resolution of symptoms, does the Holter recording need to be repeated? The answer to this key question is often found by asking two additional questions: Would repeating the Holter recording alter treatment? Will the patient's account of symptoms (i.e., the "poor person's Holter") be adequate for guiding management? In many instances, such as in this particular case, experts would consider monitoring the patient's symptoms alone to be adequate.

#### **INDICATIONS**

## Evaluation of Patients with Symptoms Possibly Related to Rhythm Disturbances

Symptoms of patients with VT or VF include palpitations (i.e., a sensation in the chest of a rapid or irregular cardiac rhythm), dizziness, and unexplained syncope. These symptoms may suggest a hemodynamically compromising arrhythmia.

However, not all patients with symptoms such as palpitations, dizziness, and syncope need Holter monitoring. An occasional episode of skipped, dropped, or racing beats is not suggestive of VT or VF. Symptom duration and severity, the likelihood of underlying cardiac disease based on a history of risk factors or echocardiogram result, the existence and effect of potentially reversible extracardiac factors (e.g., caffeine, alcohol, sleep deprivation, viral illness, electrolyte abnormalities, hyperthyroidism, nonessential medications, normal sedimentation rate), the patient's or clinician's "need to know," and cost concerns should all be considered. Therefore, on a

patient's first visit, do *not* routinely order Holter monitoring for patients who lack underlying heart disease or risk factors, especially if symptoms are of recent onset and are not particularly bothersome to the patient. On the other hand, you probably should consider some form of AECG monitoring for a patient with activity-limiting symptoms, especially when the symptoms are persistent, and especially when the patient has possible underlying structural heart disease or multiple risk factors for CAD.

Ambulatory electrocardiography can be of use in evaluating the patient with unexplained syncope, presyncope, or episodic dizziness. The most recent American College of Cardiology/American Heart Association (ACC/AHA) guidelines give a class I recommendation for an AECG in such patients "in whom the cause is not obvious" (Crawford and colleagues, 1999). Although syncope is a prevalent disorder, it is only infrequently secondary to a cardiac cause. However, mortality rate is quite high in patients with a cardiac cause of syncope, and it is an independent predictor of sudden death. (One pearl: The older the patient is with the first episode of syncope, the more likely the syncope is due to a cardiac cause and the worse the prognosis.) Unfortunately, the yield of AECG monitoring in the patient with syncope is low because most patients do not have symptoms during the time they are being monitored. In fact, it is estimated that AECG establishes a diagnosis in only 2% to 3% of syncope patients. Because syncope can be a symptom of a potentially serious underlying problem, an AECG is prudent to pursue in the high-risk patient. In the evaluation of syncope, the most appropriate type of AECG monitoring is usually the loop recorder, which can be activated by the patient once he or she regains consciousness. The higher yield of loop recorders over Holter monitors was demonstrated in a prospective randomized trial (Sivakumaran and colleagues, 2003). Sometimes results of the AECG can determine whether the patient with syncope would benefit from being evaluated in the electrophysiology laboratory. For example, the syncope patient with structural heart disease noted to have nonsustained VT on AECG has a high likelihood of having a serious underlying ventricular tachyarrhythmia induced in the electrophysiology laboratory.

Evaluation of unexplained recurrent palpitations, a widely accepted indication for AECG monitoring, was also given a class I recommendation by the ACC/AHA. Unexplained palpitations may be secondary to a potentially dangerous underlying arrhythmia, and it is prudent to identify high-risk patients. Although the diagnostic yield of identifying the cause of frequent palpitations from a 24-hour Holter monitor is approximately 35%, the percentage is doubled if one uses a loop recorder. Therefore, it is considered more cost-effective to start the AECG evaluation of palpitations with a loop recorder rather than a Holter monitor. Often (perhaps in one third of patients) a symptom is reported in the patient's symptom diary that does not correlate with any abnormality on the ECG, a scenario that is helpful to exclude a cardiac cause, reassure the patient, and consider pursuing other noncardiac causes of the patient's symptoms

Evaluation of palpitations with AECG is a special case, with insight provided in a study (Weber and Kapoor, 1996) showing that one third of patients coming to an emergency facility with palpitations as their chief complaint had a psychological cause for this symptom (either generalized anxiety or panic disorders). Four factors were found in this study to be independently predictive of a cardiac (arrhythmia) cause: male gender, a history of heart disease, subjective sensation of an irregular heartbeat, and symptom duration (palpitations) of more than 5 minutes. Awareness of these findings may help in the decision of when to order an objective form of arrhythmia detection.

#### **Evaluation of Antiarrhythmic Drug Therapy**

Although in the past AECG was commonly used to evaluate the efficacy of an antiarrhythmic drug, it is now used less frequently for this indication because interpretation is limited by a high

spontaneous variability in the frequency and type of arrhythmia within each individual, and lack of correlation between suppressing an arrhythmia and patient outcome. This limitation was particularly evident in the Cardiac Arrhythmia Suppression Trial (CAST; Echt and colleagues, 1991), in which attempted arrhythmia suppression with flecainide, encainide, and moricizine resulted in an increased mortality rate. This study outcome led to class I antiarrhythmics no longer being recommended as long-term therapy for arrhythmia suppression, resulting in less AECG monitoring. Furthermore, approximately 25% of patients with ventricular arrhythmias have spontaneous resolution within 12 to 17 months, making it difficult to establish benefit (or causality) after antiarrhythmics are started. When AECG is chosen for monitoring drug response it is done so under three specific circumstances: (1) to document drug response in a patient with known baseline of arrhythmias that are reproducible; (2) to detect proarrhythmic response to an antiarrhythmic drug; or most commonly, (3) to assess rate control in chronic atrial fibrillation.

A review of the statistics behind spontaneous variability in PVC frequency is essential if the practitioner is to use Holter recordings to evaluate the effectiveness of antiarrhythmic therapy, especially now that nonrepetitive ventricular ectopy is treated much less often than it was in the past. To *statistically* exclude a spontaneous variation in response following antiarrythmic therapy, a reduction in PVC frequency of at least 70% to 90% between Holter recordings is required.

#### **Evaluation for Silent Myocardial Ischemia**

Silent myocardial ischemia, defined as objective evidence of ischemia without chest discomfort or any anginal equivalent, is the most common manifestation of CAD. It is estimated that over 75% of ischemic episodes occur without symptoms while patients go about their activities of daily living, and because episodes of silent myocardial ischemia are not alarming to the patient, they frequently go undetected and untreated. AECG monitoring to detect ST segment changes was first investigated in the mid-1970s, but there was much skepticism, particularly regarding a high number of false-positive results. In monitoring for silent ischemia, the Holter monitor continuously records ST segments, which can be assessed for flat or downsloping ST depression of 1 to 2 mm or more (see discussion of Equipment Settings). However, because of large day-to-day variability of ST segment changes, ST segment depression as detected by Holter monitors may not be indicative of ischemia. In recent years, technologic improvements have resulted in increased specificity for ischemia particularly in certain population subgroups. We now know that ischemia detected by Holter monitoring is associated with increased coronary events and increased mortality risk, but this applies only to patients with known CAD, particularly those who have had an MI. At this point, there is no role for monitoring for silent myocardial ischemia in patients without CAD. For this reason, the ACC/AHA do not strongly support the routine use of AECG to assess for silent myocardial ischemia (with one exception being the patient with suspected variant [Prinzmetal's] angina). Furthermore, Holter monitoring should not be used as an alternative to EET to diagnose ischemia. It has been suggested that Holter monitoring may allow for further risk stratification in patients who have had a positive EET, by assessing for ischemia while patients perform their routine activities. Such detection of ischemia by Holter monitoring may help to identify groups of patients who would benefit most from more aggressive antiplatelet and antiischemic therapy.

## Risk Assessment in High-Risk Asymptomatic Patients

There are approximately 450,000 sudden cardiac deaths per year in the United States; most are due to ventricular tachyarrhythmias such as VF or VT. One key role of AECG is, in certain high-risk patient populations, to detect arrhythmias that are precursors to sudden death so that there is time to consider an intervention that may reduce the patient's chance of sudden death. Patients who survive VF or sustained VT are likely to have recurrences (particularly if they have CAD or structural heart disease), and unfortunately many such recurrences are fatal. Much attention has been given to the prevention of sudden cardiac death, particularly with the development of ICDs, which have shown a mortality risk benefit in select patient populations. Antiarrythmic drugs, although less effective in certain subgroups for primary and secondary prevention of sudden cardiac death, are often used in conjunction with ICDs to reduce the frequency of shocks.

Conditions associated with ventricular arrhythmias and sudden cardiac death include CAD, dilated or hypertrophic cardiomyopathy, right ventricular dysplasia, long QT syndrome, electrolyte abnormalities, use of antiarrhythmic drugs, and valvular heart disease. As noted earlier, AECG can be used to identify high-risk patients who may be at risk for sudden cardiac death. Currently there are only three conditions for which the ACC/AHA support (albeit weakly with class IIb recommendations) risk assessment in the absence of symptoms: post-MI patients with left ventricular ejection fraction (LV EF) less than 40%, patients with congestive heart failure, and patients with hypertrophic cardiomyopathy.

In general, patients with ischemic heart disease, especially those with a history of MI, have a very high risk for a serious or fatal arrhythmic event. Frequent and complex PVCs are an independent risk factor associated with a two- to fivefold increased risk of death after an MI. AECG (particularly Holter monitoring) is sometimes performed in post-MI patients with a low EF (<40%) as a risk assessment tool.

It is well established that patients with congestive heart failure and underlying cardiomyopathy have an increased risk of sudden death. Much attention has been paid to the possible role of AECG as a way to further identify which of these patients may or may not benefit from ICDs. However, the data are conflicting and the role for using AECG in this population is not well established.

Patients with hypertrophic cardiomyopathy have an increased risk of sudden death. AECG monitoring for nonsustained VT (NSVT) has been proposed in this patient population, with the idea that NSVT may be a marker for sudden death. However, this has not been clearly established, and arrhythmia treatment has not been shown to improve mortality risk. Therefore, AECG for risk assessment in this population remains unclear.

## Evaluation of Pacemaker or Implantable Cardioverter-Defibrillator Function

In the past, Holter monitors were commonly used to assess the function of a pacemaker or an ICD, and the data were used to guide programming, for example, by changing pacing thresholds. This practice is becoming less frequent because newer generation devices generally have the ability to store ECG data that can be retrieved and analyzed. However, AECG is still recommended in several situations, such as to evaluate for device failure or malfunction (e.g., pacemaker-induced tachycardia in the setting of frequent palpitations, syncope, or near syncope) or to assess the response to adjunctive pharmacologic therapy in patients receiving frequent ICD discharges.

#### **CONTRAINDICATIONS**

As with other office-based procedures, AECG monitoring can be overutilized. More information is not necessarily better, particularly when the information could be misleading, such as may be the case with a false-positive result in a low pretest probability setting (e.g., a low-risk patient with a constellation of vague symptoms). AECG should not be used as a screening tool in the low-risk asymptomatic

patient, or for the evaluation of chest pain in low-risk patients who can exercise. Similarly, the ACC/AHA discourages AECG for patients with syncope or palpitations in whom another etiology has been identified, or in the assessment of a patient who has had a cerebrovascular accident but with no evidence of arrhythmia.

## PREPROCEDURE PATIENT EDUCATION AND PREPARATION

- Explain to the patient why Holter or event monitoring is necessary.
- Explain to the patient the need for a symptom diary.

An essential part of the Holter recording is the patient's symptom diary. Consider how often supraventricular and ventricular ectopy are found in the general population as well as how frequently patients come to a clinician with symptoms suggestive of cardiac arrhythmias; the importance of establishing a cause-and-effect relationship between the two should be evident. For example, if symptoms are noted at 10 AM, 2 PM, 5 PM, and 11 PM, but no cardiac arrhythmias are seen at these times, it is unlikely that the symptoms are cardiac related. Therefore, much useful information may be obtained from Holter recordings even in the absence of arrhythmias—provided the diary is completed carefully.

In symptomatic individuals who actually demonstrate cardiac arrhythmias on Holter monitoring, one can determine whether the arrhythmias are likely to be the cause of their symptoms by the temporal relationship in the diary. For example, if long runs of ventricular bigeminy occur while the patient is relaxed and totally unaware of the arrhythmia—and palpitations or chest discomfort are noted only during periods of sinus rhythm—ventricular bigeminy is probably not related to the patient's symptoms.

Unfortunately, in clinical practice, completion of the diary is all too often neglected. As a result, consider the following:

- Emphasize the importance of filling out the diary to your patient.
- Be sure that the patient can read and write before providing the diary. If the patient is illiterate, see if someone can help the patient fill out the diary.
- For hospitalized patients, consider actively involving the nursing staff to ensure accurate completion of the patient diary.

**NOTE:** Use of event monitoring is much more conducive to correlating symptoms with arrhythmias than Holter monitoring because the occurrence of symptoms is what prompts the patient to initiate the event monitor recording.

#### **EQUIPMENT**

- Holter, event, or other AECG monitor with desired capabilities (check for cracked or broken wires and for damage to the carrying case)
- Fresh, alkaline batteries
- Printer paper, ink, extra cassettes (for the Holter report to be printed out for interpretation)
- Razor
- Rubbing alcohol
- Electrodes
- Lead attachment kit

Most of the time, hospitals and commercial Holter or event laboratories employ trained technicians to scan Holter recordings for the interpreting clinician. This is a tremendous time-saving feature because the technician can highlight the principal findings, thus sparing the clinician the need to meticulously scan each of the full-disclosure printouts.

On the other hand, the luxury of having a trained technician to scan tracings is not available to many clinicians who have purchased

their own Holter monitoring system. In this case options include the following:

- Having the hard copy of the Holter recording processed and scanned by a commercial laboratory—an expensive and rarely used option.
- Hiring or training a technician to scan, which may be the most cost-effective solution for the busy practitioner who has a nurse or technician with interest and expertise in arrhythmia interpretation.
- Not printing 24-hour full disclosure. (Full disclosure means that the Holter device prints out a miniaturized strip of each hour of the 24-hour tracing.) Depending on the area's third-party payment regulations, the practitioner may not receive full reimbursement unless 24-hour full disclosure is printed out.
- Printing but ignoring the 24-hour full disclosure, or looking only
  at those portions of the printout that seem relevant to the clinical problem (i.e., looking at full disclosure only at times when
  symptoms are noted in the diary, or at times of densest ectopy as
  suggested on the hourly summary). This saves time, but if something is missed, it will be documented.
- Printing 24-hour full disclosure and scanning the printout yourself. Although this takes a greater amount of time to accomplish, it may be time well spent.
- Purchasing a Holter system that does not provide full disclosure. If reimbursement for this modality in your area is comparable to that for full-disclosure systems, this alternative may be both cost and time effective, especially if the practitioner does not have great interest or expertise in arrhythmia interpretation. However, such systems are more likely to yield equivocal findings, and they may overlook potentially important arrhythmias. Personal interpretation of Holter data recorded on such systems is only as good as the system's computer software.

**NOTE:** The authors feel that full 24-hour disclosure is indispensable for optimal Holter interpretation. Many experts suggest that it is essential for the interpreter to scan the entire recording, even when trend analyses, hourly summaries, and selected rhythm strips are normal

Systems that offer data compression do not provide full disclosure. Using signal averaging to evaluate "compressed" data, and then re-expanding it, does not allow every QRS complex to be reproduced.

#### **TECHNIQUE**

- The patient's report form (see Fig. 87-14) should be completed with relevant patient information such as date of birth and indications for procedure. Recorded data such as cardiac risk factors, medications, activity level, and other medical problems that may affect the management following interpretation would also be helpful.
- 2. Monitoring parameters on the equipment should be set.
- Attach the ECG electrodes in the locations indicated for the particular model of Holter or event monitor (see the operating instructions or illustrations provided by the monitor manufacturer). In general, limb leads are placed more centrally than with an office ECG.

#### **Equipment Settings**

Most Holter systems provide the operator some flexibility in selecting the parameters used to scan for abnormalities. Some routine settings are shown in Table 87-1. In this example, the computer will record a full-size rhythm strip for those tachycardias that are faster than 120 beats per minute (automatic high rate); for bradycardias slower than 40 beats per minute (automatic low rate); and for pauses longer than 2 seconds (automatic pause). Since automatic abnormal is set at three events, the machine should record the first three

TABLE 87-1 Equipment Set	ttings
Automatic high rate	120 bpm
Automatic low rate	40 bpm
Automatic pause	2.00 sec
Automatic supraventricular ectopic	25%
Automatic ST level	2 mm
Automatic abnormal	3/hr
Periodic storage	2 hr
Strips per hour	5

incidents of tachycardia that occur during any given hour, to a maximum of five strips per hour for any reason—which may potentially yield a total of 120 rhythm strips to review (up to 5 strips per hour  $\times$  24 hours = 120 strips).

Because periodic storage is set at 2 hours, the computer should record at least 1 rhythm strip every 2 hours, even if no abnormalities occur. This guarantees that the interpreter will have at least 12 rhythm strips to view, even if the Holter result is completely normal.

**NOTE:** The authors are generally uncomfortable accepting the computer's reading of "normal" unless a minimal number of normal full-size rhythm strips are displayed.

One reason for favoring 120 beats per minute as the upper rate limit is that lower numbers (e.g., 100 or 110 beats per minute) are more likely to produce an excessive number of benign sinus tachycardia strips, whereas higher numbers (e.g., 130 or 140 beats per minute) might prevent the detection of significant tachycardias with relatively slow rates, such as VT at 125 beats per minute.

**NOTE:** Selection of equipment settings always involves a compromise, and the setting of 120 beats per minute may occasionally yield a monotonous deluge of sinus tachycardia strips at 120 to 125 beats per minute.

For similar reasons, a lower rate limit of 40 beats per minute is favored. For example, selecting a lower rate limit of 50 beats per minute might result in a deluge of benign sinus bradycardia strips if the Holter examination was performed on an otherwise healthy individual who happened to have a slow resting heart rate.

Pauses of up to 2 seconds are common, especially in the elderly, and are usually benign. Longer pauses, especially those accompanied by frequent episodes of bradycardia with rates of fewer than 40 beats per minute, suggest the possibility of sick sinus syndrome, particularly in the setting of structural heart disease.

The automatic supraventricular ectopic (SVE) setting of 25% should record rhythm strips demonstrating a greater than 25% variation in R-R interval. This record is how atrial fibrillation or premature atrial contractions (PACs) are detected. Setting the SVE lower (e.g., at 10%) would detect many more PACs but would also pick up sinus arrhythmia. Higher settings might miss too many PACs. Even with a setting of 25%, imagine the number of strips that would result when the underlying rhythm is atrial fibrillation!

The most controversial parameter is the automatic ST segment level, which is usually set at 2 mm, unless the reason for performing the Holter monitoring is to "seek and search for" silent ischemia (which is only recommended in the known CAD patient). Resolution of ST segment images may be less than ideal, and because of marked day-to-day variability of ST segment changes, in an otherwise unselected population the majority of episodes of ST segment depression between 1 and 2 mm will be false-positive results; that is, they will not represent true silent ischemia. Setting the ST segment parameter at 2 mm greatly increases the specificity for true silent ischemia. The tradeoff is that some patients with CAD may have frequent episodes of silent ischemia with lesser degrees of ST segment depression. Although the ST segment trend analysis (see Fig. 87-4) should reflect this, it is important to document the phenomenon by recording at least a few full-size strips that demonstrate

definite ST segment depression. This is one benefit of lowering the ST segment parameter to 1 mm when the principal reason for performing the Holter test is to evaluate the patient with known CAD for silent ischemia.

**NOTE:** The technique and equipment settings for event monitors are usually similar to those for Holter monitors.

#### INTERPRETATION OF RESULTS

Appreciation of the wide range of normal is essential for meaningful interpretation of ambulatory ECG recordings. Premature supraventricular and ventricular contractions, as well as certain other cardiac arrhythmias, are common in otherwise healthy, asymptomatic individuals without underlying structural heart disease or CAD. Additional evaluation of such individuals is potentially expensive and may be harmful.

Although a detailed description of all of the variants of "normal" is beyond the scope of this chapter, a brief discussion of the prevalence of ventricular arrhythmias and then an overview of the clinical perspective of the process may be helpful.

## Prevalence of Premature Ventricular Contractions in the General Population

Premature ventricular contractions are common. They are found in up to 50% of otherwise healthy, asymptomatic young adults. Their frequency increases with age; thus most adults over 60 have some ventricular ectopy during a 24-hour period of monitoring. Less well appreciated is the fact that in the absence of underlying heart disease, complex forms of ventricular ectopy (e.g., ventricular couplets, salvos, or longer runs of VT) are uncommon and when present in this population are generally associated with low risk of sustained VT or sudden death. The excellent prognosis for such patients has been documented in patients with primary electrical disease (Kennedy and colleagues, 1985) and competitive athletes. In contrast, both frequent and complex ventricular ectopy are common when underlying heart disease is present.

The term *frequent* when used to quantify ventricular ectopy is subject to interpretation. In a population of middle-aged individuals with underlying heart disease, frequent ventricular ectopy is most often defined as an average of more than 10 to 30 PVCs per hour over 24 hours of monitoring (i.e., at least 240 PVCs per day). In contrast, among otherwise healthy, asymptomatic young adults, a much lower number to define *frequent* should probably be used. As noted earlier, although up to half of these individuals have some PVCs during 24 hours of monitoring, it is unusual for them to have as many as 100 PVCs per day.

## Clinical Significance of Premature Ventricular Contractions

The significance of ventricular ectopy depends on the clinical setting in which it occurs. Patients with PVCs who do not have underlying heart disease tend to have a benign prognosis. Even among individuals with primary electrical disease and frequent, complex PVCs (as noted previously), treatment may not be indicated in the absence of both symptoms and underlying heart disease, as demonstrated by the Cardiac Arrythmia Suppression Trials (CAST I and II), which found that antiarrhythmic treatment was associated with an increased mortality rate.

In a study of 355 athletes ages 14 to 35 years of age who underwent a 24-hour Holter study because of palpitations or frequent PVCs noted on routine ECG (Biffi and colleagues, 2002), there were no deaths during a mean 8-year follow-up in the group (284 athletes) noted to have fewer than 2000 PVCs in 24 hours. The 71 athletes who had 2000 or more PVCs per day were excluded from competitive athletics. There was only one sudden death in this

excluded group in an individual with arrhythmogenic right ventricular cardiomyopathy; it occurred while playing field hockey against medical advice.

In contrast, in the setting of acute ischemia, especially if associated with angina, any ventricular ectopy at all must be viewed as significant and as a potential trigger of VF. Data suggest that this is particularly true of PVCs that occur in recovery following exercise, for example, during exercise ECG (stress) testing (Dewey and colleagues, 2008).

Although left ventricular function is the most important predictor of death during the year following acute MI, PVCs are also an independent risk factor. Death in this year is related to the frequency of ventricular ectopy, as detected by Holter monitoring before discharge from the hospital. Patients with less than one PVC per hour tend to have a low (<10%) mortality rate. This figure rises sharply as a function of PVC frequency. About half of the total PVC-associated deaths happen at PVC frequencies as low as three per hour. A mortality rate plateau (20% to 30% for the ensuing year) is reached above PVC frequencies of 10 per hour. Thus, a predischarge Holter monitor recording obtained for a post-MI patient needs to be interpreted in a different light than that of one obtained on a patient with chronic ventricular ectopy. The definition of "frequent" ventricular ectopy should probably be adjusted downward in post-MI patients.

The frequency of ventricular arrhythmias detected in the postinfarction period is time dependent. PVCs are infrequent for 3 to 5 days following infarction. They tend to increase in frequency over the next 6 to 12 weeks, and then the frequency levels off. Despite the tendency of PVC frequency to increase after discharge from the hospital, it may be more practical to obtain a baseline Holter monitor in selected patients *before* they go home.

Repetitive forms of ventricular ectopy (e.g., ventricular couplets, and especially salvos and longer runs of VT) are additional cause for concern. Their presence more than doubles the first-year mortality risk after MI over that of patients who do not demonstrate repetitive forms. In contrast to previous thinking, multiform PVCs and R-on-T complexes are considered much less worrisome than repetitive forms.

Much less can be said about the clinical benefit of drug treatment for PVCs in postinfarction patients. Beta-blockers are generally favored as first-line therapy because they are well tolerated, have a low proarrhythmia effect, and reduce both postinfarction mortality and ventricular ectopy rates. As mentioned, the CAST studies demonstrated a two- to threefold increase in mortality rate when postinfarction patients with ventricular arrhythmias were routinely treated with flecainide or encainide. Treatment of such patients with a class Ia, Ib, or Ic antiarrhythmic agent when beta-blockers cannot be used is not recommended. Because these antiarrhythmic drugs may produce significant side effects, increase mortality risk, or be proarrhythmic or ineffective, the decision to use them should never be taken lightly.

Fortunately, there are alternatives to pharmacologic therapy. ICDs are often lifesaving, but expensive, and may be associated with morbidity from repetitive shocks. That said, ICDs are often recommended in patients with prior MI who have an EF less than 30%, and in survivors of sudden cardiac arrest. Most patients with VT and normal LV function may not require or be candidates for ICDs. Catheter ablation of the ectopic focus or reentry circuit is another potential alternative in some of these patients.

#### **SAMPLE HOLTER MONITOR**

Many types of Holter monitor systems are on the market. Each has its own advantages and disadvantages. The field continues to evolve at an amazingly rapid pace, so that current drawbacks of a particular system may be corrected by the next version of that system. It behooves the interested clinician to become familiar, at least in general terms, with the pros and cons of several types of Holter

systems. This familiarity will assist the clinician in selecting those operative features that are likely to be most applicable for a particular practice setting.

In the following section, the information provided by one particular full-disclosure Holter system is illustrated. Although resolution quality of P wave and ST segment morphology is admittedly less than optimal with this system, it should still be adequate for office monitoring. The general principles illustrated by this Holter system are applicable to other systems, as well as to many of the principles involved in event monitoring. The main difference with event monitoring is that 24-hour full disclosure is not included.

#### **CASE STUDY**

A 60-year-old man has dyspnea on exertion, which has been increasing for 1 month. He had an MI in the distant past, but he has been active for years and is otherwise doing well and is not on cardiac medications. He has not complained of chest pain or palpitations but recently described frequent episodes of intense dyspnea, weakness, and dizziness, most often associated with activity. Physical examination is unremarkable, and a resting ECG reveals normal sinus rhythm without any acute changes. Because of the frequent occurrence of symptoms with activities of daily living, the practitioner has decided to obtain a Holter monitor before exercise testing.

#### **Patient Diary**

It is important for patients to keep a diary to aid in interpreting the results of Holter monitoring. As mentioned earlier, symptoms of potential cardiac etiology and arrhythmias are common in the general population. The only way to prove that symptoms are cardiac related is to document a temporal correlation between their occurrence and the occurrence of arrhythmias on a Holter monitor.

As emphasized earlier, completion of a diary can provide the clinician with much useful information, even if the Holter result is entirely normal. Thus, if multiple symptoms are noted on the day of monitoring and no arrhythmias are detected on the Holter, the patient can be reassured that symptoms are unlikely to be cardiac in origin. The diary (Fig. 87-1) is especially helpful in this case because it indicates eight symptomatic episodes of weakness, dizziness, or shortness of breath.

#### 12-Lead Electrocardiogram

Many clinicians obtain a preprocedure 12-lead ECG on all patients scheduled for Holter monitoring to screen for baseline artifact. If there is significant artifact on the 12-lead ECG, such artifact will likely be seen on the Holter recording and might preclude accurate assessment of the rhythm strip. However, this additional step may

Time	Activity	Symptoms
1PM	Lunch, relax	
2PM	Rake leaves	Weak, dizziness
4PM	Sitting, resting	Weak, dizziness
6PM	Resting	Weak
7PM	Watching TV	Dizziness
9PM	Went to bed	Dizziness
7AM	Breakfast	Short of breath
8AM	Resting	Short of breath, dizzy
9AM	Drove to doctor's office	Weak, dizziness

Figure 87-I Patient diary for Holter monitoring.

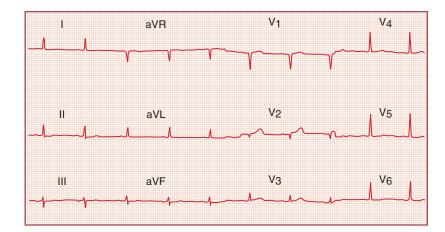

Figure 87-2 Baseline 12-lead electrocardiogram.

be considered unnecessary and time consuming by technicians because the patient has usually undergone a 12-lead ECG at a recent clinical visit. In most cases, proper attention to lead placement precludes baseline artifact.

If there has been a frequent problem with the quality of Holter results, certain systems offer the ability to test the three or five leads of a Holter recording through a 12-lead ECG at the time of lead attachment. Others require the use of a "block," a conversion device available from the manufacturer, to connect the Holter monitor to a 12-lead ECG for testing.

In this case example, despite the fact that the P wave amplitude is small on the patient's 12-lead ECG (Fig. 87-2), the underlying rhythm fortunately turns out to be clearly identified as sinus on the eventual Holter (since the P wave is upright in lead II). Although this overall Holter study is interpretable, on many of the selected rhythm strips, as predicted by the 12-lead, a sinus rhythm is harder to identify with certainty.

Other benefits of obtaining a baseline 12-lead ECG include accurate determination of intervals (PR, QRS, and QT), and a much better appreciation of the baseline ST segment (many patients have baseline ST depression, which is not indicative of ischemia). As a result, determination of ST segment shifts (i.e., possible silent ischemia) is greatly facilitated. In this Holter study example, all intervals are normal. There is some nonspecific ST-T wave flattening in the inferolateral leads, but no significant ST segment depression and no acute changes.

#### **Narrative Summary**

Some Holter monitors produce a narrative summary (Box 87-1) that consolidates the principal findings detected by the computer. Practically speaking, the main task of the interpreter is to verify that this computed summary of pertinent findings is accurate.

In this case example, the narrative summary indicates a number of abnormal findings. The interpreter will certainly want to see representative samples of the following:

- Episodes of tachycardia (with a heart rate of up to 160 beats per minute)
- Episodes of bradycardia (with a heart rate between 36 to 39 beats per minute)
- Pauses (between 2.14 and 3.29 seconds in duration)
- Rhythm strips at the time the patient activated the event button (which occurred on two occasions)
- "Abnormal beats" (1151 were detected), including the two episodes of "successive abnormal episodes"

The clinician-interpreter does not need to find each of the 1144 abnormal beats. Nevertheless, he or she should verify that the beats are truly abnormal (not artifactual), whether the "abnormal" beats

are truly PVCs, and whether these PVCs seem to be occurring frequently enough to explain the computer count. Practically speaking, it matters little if there are 1144 abnormal beats or 1100 abnormal beats—or 800 or 500, for that matter—since the difference between 1151 and 800, or 500, is still well within the range for spontaneous variability. Clinically, it is unlikely that treatment would differ for a patient who has 1151 PVCs or 500 PVCs. In both situations, it is probably sufficient to say that there are "frequent" PVCs.

**REMEMBER:** Evaluate any intervention; a reduction of at least 70% to 90% of the PVCs from one Holter to the next must be demonstrated to rule out the possibility of spontaneous variation. Therefore, in this particular case, the number of PVCs would have to be reduced from 1144 to *less than* 350 to eliminate this possibility.

Finally, this particular Holter system does not indicate whether the PVCs are uniform or multiform; it simply gives the sum of all

## Box 87-1. Narrative Summary of Holter Recording\*

- During this period the average heart rate was 75 bpm with a maximum heart rate of 160 bpm at 16:45 and a minimum heart rate of 36 bpm at 03:38.
- There were 29 tachycardic episodes detected during the monitoring period.
- These episodes ranged in rate from 120 bpm to 160 bpm.
- There were 7 bradycardic episodes detected during the monitoring period.
- These episodes ranged in rate from 36 bpm to 39 bpm.
- There were 57 pause episodes detected during the monitoring period.
- These episodes ranged in duration from 2.14 sec to 3.29 sec.
- There were 25 SVE episodes detected during the monitoring period.
- The patient pressed the event button two times during the monitoring period.
- There were no ST segment episodes detected during the monitoring period.
- During the monitoring period there were 1144 abnormal beats detected.
- There were two successive abnormal episodes detected during the monitoring period.

SVE, supraventricular ectopy.

<sup>\*</sup>The patient was monitored for a period of 23:36 (hours and minutes).

"abnormal" beats. Once again, practically speaking, this really does not matter in view of the following facts:

- The prognostic implications of multiformity are not nearly as ominous as previously thought. Much more important than multiform PVCs are repetitive PVCs (e.g., couplets, salvos, and longer runs of VT).
- Almost all individuals with frequent ventricular ectopy over a 24-hour period demonstrate at least some degree of multiformity.

#### **Trend Analysis of Abnormal Beats**

The trend analysis of abnormal beats allows the interpreter, at a glance, to see what time of day PVC frequency peaks. In this case, minimal ventricular ectopy occurs at night and maximal ectopy occurs during the daytime and evening hours (e.g., between noon and midnight) when the patient is active (Fig. 87-3).

Identifiable periods of peak ventricular ectopic activity may suggest a specific approach to treatment. For example, patients who manifest diurnal variation or increased ectopic activity during the hours of maximal daily activity often have an increase in sympathetic tone as part of their etiology. Therefore, these patients are optimal candidates for beta-blocker therapy. Patients on antiarrhythmic therapy who demonstrate a peak in ectopic activity 6 to 10 hours after the last dose of their medication may benefit from an increased dosing frequency or by use of a sustained-release product.

## Trend Analysis of Heart Rate and ST Segment Level

The heart rate trend analysis demonstrates, at a glance, heart rate variations throughout the day. In this case, it is easy to see that a tachycardia of approximately 150 beats per minute was sustained for most of the period between 16:00 and 17:00 (Fig. 87-4). The ST segment level trend analysis shows that 1 mm of ST segment depression was sustained throughout much of this same period (*arrow*), suggesting that the ST segment depression is likely to be at least partially rate related.

The ST segment level trend analysis may facilitate quantitative assessment of the type and duration of ST segment depression in patients with silent ischemia.

#### **Hourly Summary**

Most Holter systems produce an hourly summary in some type of tabular format. Although it usually takes some time and practice to become familiar with this type of format, doing so tremendously facilitates interpretation. The hourly summary shows exactly where to look on the full-disclosure tracings to verify abnormal findings.

The hourly summary in this case (Fig. 87-5) indicates the following:

- The lowest heart rate (36 beats per minute) was recorded between 03:00 and 04:00. The fastest heart rate (160 beats per minute) was recorded between 16:00 and 17:00. The greatest hourly frequency of PVCs, or "isolated abnormalities," (235) occurred between 16:00 and 17:00.
- The event button was activated twice (once between 15:00 and 16:00, and once between 09:00 and 10:00).
- All 57 pause episodes (38 + 19) occurred between 19:00 and 21:00.

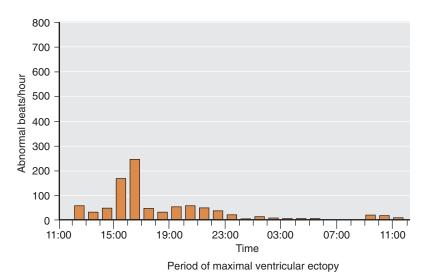

#### Selected (Full-Size) Rhythm Strips

Inspection of selected representative full-size rhythm strips is essential for verifying pertinent computer findings and is generally performed next. These strips have usually been selected by the reviewing technician as discussed previously. The rhythm strips should include portions of the tracings that were patient activated (i.e., the patient was symptomatic at the time the device recorded the strip) as well as abnormalities noted by the technician. Thus, in this case, the patient had a 10-beat run of paroxysmal atrial fibrillation at 13:03:20 (Fig. 87-6). He was in a regular, presumably sinus rhythm of 80 beats per minute at 15:03:20 (Fig. 87-7). An ever-so-slightly irregular supraventricular tachycardia (rapid atrial fibrillation) is evident at 15:51:09 (Fig. 87-8).

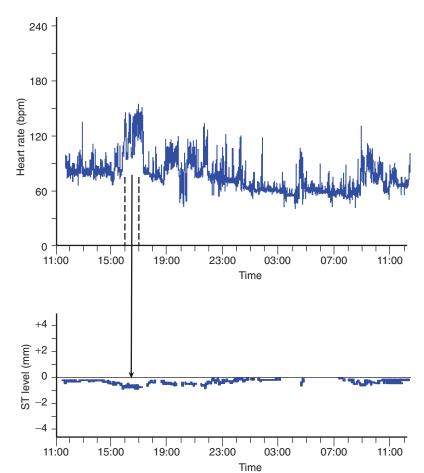

Another rhythm strip was automatically recorded at 15:55:53 (Fig. 87-9), presumably because of the rapid, irregular rhythm and associated ectopic activity. Finally, a rhythm strip is shown at 21:56:13 (Fig. 87-10) when the computer probably interpreted the tracing, mistakenly, as representing ventricular ectopic beats. Close inspection suggests that the baseline irregularity is in fact due to artifact.

#### **Full-Disclosure Strips**

Many insurance carriers now require full disclosure as a prerequisite for maximal financial compensation. The obvious benefit of full disclosure is that it enables the interpreter to review any or all events of the day. The interpreter can also print out a full-size rhythm strip of any abnormality not initially recognized by the computer or technician. Interpretation of full-disclosure tracings probably seems like an overwhelming task to the uninitiated; however, this need not be the case.

Figure 87-10 Selected rhythm strip at 21:56:13.

For orientation to full-disclosure tracings, portions of three pages from the case example Holter study are displayed. Normally, each page contains a miniaturized account of a full hour of Holter recording from a single monitoring lead. One minute of recording is represented by each of the 60 lines on the page. Because of space constraints for this chapter, only half of a page (30 minutes) is used for each demonstration. Thus, the period from 13:00 to 13:29 is shown in Figure 87-11; from 15:30 to 15:59 in Figure 87-12; and from 16:00 to 16:29 in Figure 87-13.

A scan of the first few lines of Figure 87-11 shows how relatively easy it is to identify the short run of supraventricular tachycardia that occurs between 13:03:10 and 13:03:20. (See Fig. 87-6 for the full-size recording of this short burst of tachycardia.) Also note how easy it is both to spot the "different looking" (i.e., abnormal) beats, which are PVCs, and to see that the baseline undulation on the 13:06 and 13:12 lines is likely due to artifact.

With practice, self-discipline, and diligent concentration, the interpreter should be able to scan each page (i.e., each hour of recording) rapidly (in <10 seconds) and still be able to identify most major abnormalities on the page.

Now look at Figure 87-12. The selected full-size rhythm strips previously reviewed demonstrated rapid atrial fibrillation at 15:51:09

(see Fig. 87-8) and rapid atrial fibrillation with frequent ventricular ectopy at 15:55:53 (see Fig. 87-9). Find these arrhythmias on the full-disclosure tracing.

Once a particular abnormality has been seen on the miniaturized full-disclosure tracing, it becomes relatively easy to spot other episodes of that abnormality. Thus, other short runs of frequent ventricular ectopy on lines 15:52, 15:53, 15:54, and 15:56 are easily noticed. Finally, look at Figure 87-13. Note how the patient has a sustained tachycardia for a substantial portion of this monitoring period. Actual-size rhythm strips reveal persistence of rapid atrial fibrillation during much of the hour.

#### INTERPRETATION OF CASE STUDY

This case study is an excellent example of how to use a Holter system to determine the cause of a patient's symptoms. In this case, the patient's symptoms were not well defined; they included increasing dyspnea, weakness, and dizziness over the previous month. There were no palpitations, and apart from some nonspecific ST-T wave changes, the patient's baseline ECG was unremarkable. With this history, although most clinicians would include a cardiac arrhythmia in the differential diagnosis, other possibilities would merit

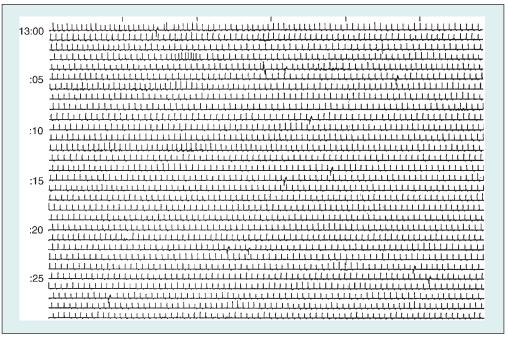

Figure 87-11 Full-disclosure strip between 13:00 and 13:29.

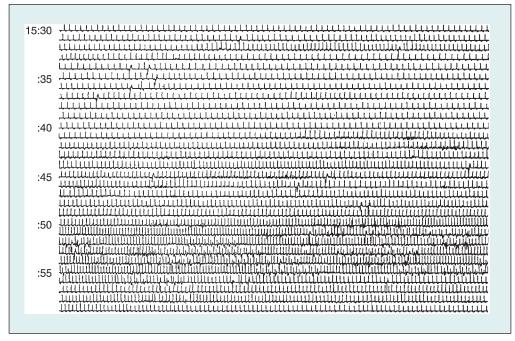

Figure 87-12 Full-disclosure strip between 15:30 and 15:59.

equal attention. However, after combining the results of this Holter data with the diary, there is little doubt as to the final diagnosis.

#### **Final Interpretation**

- Sinus rhythm with periods of sinus bradycardia down to 36 to 40 beats per minute.
- Several episodes of rapid, paroxysmal atrial fibrillation lasting minutes, with heart rate up to 160 beats per minute.
- Normal intervals.
- No significant ST segment shifts.

- Frequent PVCs (1144 recorded), especially during the waking hours—but virtually no repetitive forms.
- Diary indicates eight symptomatic episodes of weakness, dizziness, and dyspnea that correlate precisely with episodes of rapid, paroxysmal atrial fibrillation. These findings strongly suggest that the patient's symptoms are cardiac related (and should be treated).

Despite notation on the narrative summary of 57 pause episodes of up to 3.29 seconds, close inspection of full-disclosure tracings did not reveal any sustained pauses, suggesting that this count may reflect computer error.

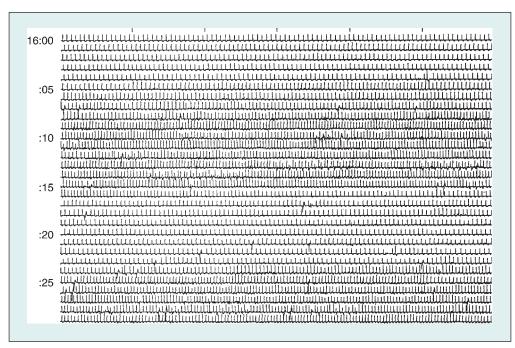

Figure 87-13 Full-disclosure strip between 16:00 and 16:29.

#### **Standard Interpretation Form**

Use of a standardized form greatly facilitates the task of Holter interpretation. The two-sided form (Fig. 87-14) organizes the key components of an ambulatory ECG study. In so doing, it not only saves time, but also ensures consistency in interpretation, provides clear documentation of findings, and facilitates the reporting of information in an easily understood, clinically relevant manner.

Several components of this form deserve special mention. Because artifact is often misread by the computer as ventricular ectopy, a boxed commentary (under "Arrhythmias") is included on the form to reflect the interpreter's assessment of the computer's PVC count. The interpreter should indicate whether the count is likely to be accurate or a distortion produced by artifact. Rather than focusing exclusively on the number of ectopic beats, a greater emphasis is placed on whether the occurrence of premature atrial, junctional, and ventricular contractions (including couplets and runs of VT) is "common," "occasional," or "rare/absent."

Finally, it is occasionally difficult to convey the clinical relevance of a patient's diary, especially when attempting to correlate it with the ambulatory ECG recording. The relative scales on the back of the interpretation form help resolve this problem. They attempt to clarify the interpreter's assessment of the validity of the patient's diary and the correlation (if any) between patient symptoms and the arrhythmias that are noted.

#### **ICD-9-CM DIAGNOSTIC CODES**

- 412 Old MI (healed; past MI diagnosed on ECG, but currently no symptoms)
- 414.01 Coronary atherosclerosis, of native coronary artery
- 414.02 Coronary atherosclerosis, of autologous vein bypass graft
- 414.04 Coronary atherosclerosis, of artery bypass graft
- 414.8 Chronic coronary insufficiency
- 426.3 Left bundle branch block, complete
- 426.4 Right bundle branch block
- 426.7 Anomalous atrioventicular excitation (Wolff-Parkinson-White syndrome)
- 426.9 Conduction disorder, unspecified
- 426.11 Atrioventricular block, first degree
- 426.12 Atrioventricular block, Mobitz type II
- 426.13 Atrioventricular block, Mobitz type I (Wenckebach's)
- 426.82 Long QT syndrome
- 427.0 Paroxysmal supraventricular tachycardia
- 427.1 Paroxysmal ventricular tachycardia
- 427.5 Cardiac arrest
- 427.31 Atrial fibrillation
- 427.32 Atrial flutter
- 427.41 Ventricular fibrillation
- 427.60 Premature beats, unspecified
- 427.61 Supraventricular premature beats
- 427.69 Ventricular premature beats, contractions, or systoles
- 427.81 Sinoatrial node dysfunction, sick sinus syndrome, sinus bradycardia
- 427.89 Other rhythm disorder, including bradycardia
- 428.1 Dyspnea, cardiac, also includes left-sided heart failure
- 780.2 Syncope, presyncope and collapse, including vasovagal and cardiac syncope
- 780.4 Dizziness
- 785.1 Palpitations

#### **CPT/BILLING CODES**

#### **Holter Monitor Studies**

93224 Wearable electrocardiographic rhythm derived monitoring for 24 hours by continuous original ECG waveform recording and storage, with visual superimposition scanning; includes recording, scanning analysis with report, physician review, and interpretation

- 93225 Recording (which includes hook-up, recording, and disconnection)
- 93226 Scanning analysis with report
- 93227 Physician review and interpretation
- 93230 Wearable electrocardiographic rhythm derived monitoring for 24 hours by continuous original ECG waveform recording and storage, without superimposition scanning using a device capable of producing a full miniaturized printout; includes recording, microprocessor-based analysis with report, physician review, and interpretation
- 99231 Recording (which includes hook-up, recording, and disconnection)
- 99232 Microprocessor-based analysis with report
- 99233 Physician review and interpretation
- 93235 Wearable electrocardiographic rhythm derived monitoring for 24 hours by continuous computerized monitoring and noncontinuous recording, and real-time data analysis using a device capable of producing intermittent full-size waveform tracings, possibly patient activated; includes monitoring and real-time data analysis with report, physician review, and interpretation
- 93236 Monitoring and real-time data analysis with report
- 93237 Physician review and interpretation
- 93268 Wearable patient activated electrocardiographic rhythm derived event recording with presymptom memory loop, 24-hour attended monitoring, per 30-day period of time; includes transmission, physician review and interpretation
- 93270 Recording (includes hook-up, recording and disconnection)
- 93271 Monitoring, receipt of transmission, and analysis
- 93272 Physician review and interpretation

#### Cardiac Pre-Event ("Loop Recorder") Studies

93268 Patient demand single or multiple event recording with presymptom memory loop, per 30-day period; includes transmission, physician review, and interpretation

# Noninvasive Venous and Arterial Studies of the Lower Extremities

Grant C. Fowler • Bal Reddy

The accuracy of noninvasive vascular studies depends not only on the skills of the operator and the interpreter, but also on the quality of the equipment or assay. That said, with state-of-the-art equipment or laboratory tests, many clinicians will manage anticoagulation therapy on the basis of noninvasive venous studies, alone, and some vascular surgeons will perform arterial surgery without preoperative arteriography.

The literature has clearly demonstrated the accuracy and benefit of compression ultrasonographic scanning, or duplex ultrasonographic scanning if it is available, in the emergency department. This is often performed by emergency medicine clinicians to exclude deep venous thrombosis (DVT). As a result, ultrasonography has basically become the standard of care for excluding DVT in the emergency department (see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]). As more primary care clinicians become comfortable performing duplex scanning, there is little doubt that they will extend its use into arterial and other studies.

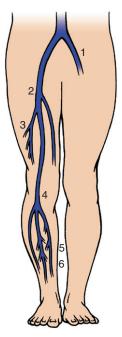

In the remainder of the hospital and in vascular laboratories, duplex or color Doppler ultrasonography has basically become the standard for evaluation of lower extremity veins; computed tomography (CT) or magnetic resonance (MR) angiography has become the standard for evaluation of arteries. Not only have older noninvasive techniques been replaced, but venography has also essentially been replaced by duplex ultrasonographic studies; consequently, the risk of complications from invasive techniques and contrast dye has decreased. However, it should be noted that many vascular laboratories continue to use older noninvasive techniques for veins because duplex or color Doppler ultrasonography is not always available. Most centers can afford only one or two duplex units, and they are often kept very busy. In some settings, the cost of equipment for even one duplex or color Doppler ultrasonography unit is prohibitive. In the meantime, very sensitive D-dimer assays have become available with algorithms that can be used to effectively rule out DVT. These algorithms can be used in conjunction with older noninvasive diagnostic techniques; consequently, these techniques remain in this chapter. Older noninvasive techniques may yet see a resurgence in popularity because not only is there evidence supporting their use, but they are very cost effective and less operator dependent. In fact, they may find permanent use as a preliminary screening test to determine who should undergo compression ultrasonographic, duplex, or color Doppler scanning.

#### **NONINVASIVE VENOUS STUDIES**

Each year in the United States, approximately 200,000 patients die from a pulmonary embolus. DVT can be found in about 80% of

patients with a pulmonary embolus. See Figure 88-1 for the most common sites for DVT; the incidence increases with age, and DVT is more common in women. One third to one half of patients older than 40 years of age who experience an acute myocardial infarction, a hip fracture, major surgery (especially orthopedic, pelvic, or urologic), or a stroke develop venous thrombi. Box 88-1 lists traditional risk factors in hospitalized patients. Lower limb DVT affects 1% to 2% of hospitalized patients. In addition, as a result of previous DVT, the prevalence of postphlebitic sequelae in the adult population is estimated to be 5%.

Early diagnosis of DVT is important because approximately 50% of untreated proximal DVT cases will result in a pulmonary embolism. Diagnosis of DVT is also important to minimize long-term complications such as venous stasis or ulceration from chronic venous insufficiency. Accurate diagnosis is crucial to limit anticoagulation therapy to those who really need it. Venous thrombi usually arise at bifurcations and in valve cusps. An aging thrombus

**Figure 88-1** Six most common sites of deep venous thrombosis (DVT) in the lower body. I, Left iliac vein; 2, common femoral vein; 3, termination of deep femoral vein (profunda femoris); 4, popliteal vein at adductor canal; 5, posterior tibial vein; 6, intramuscular veins of calf.

#### Box 88-1. Traditional Risk Factors for Deep Venous Thrombosis (Especially in Hospitalized Patients)

Acute myocardial infarction

Acute respiratory failure

Acute stroke with paresis

Blood type (persons with type A may be at higher risk than those with type O)

Fractures, especially spine, pelvis, long bone fractures, or multiple fractures

Heart disease, especially congestive heart failure

Hypercoagulable states

Local injury to veins

Malignancy

Mechanical ventilation

Myeloproliferative disorders

Nephrotic syndrome

Oral contraceptive use

Paroxysmal nocturnal hemoglobinuria

Persons older than 40 years of age

Persons with paralysis or otherwise immobilized

Postoperative state from major surgery

Pregnancy or postpartum, especially postcesarean section

Previous DVT or pulmonary embolism

Trauma

Ulcerative colitis or Behçet's syndrome

Venous stasis

can adhere to the vein wall and damage or destroy nearby valves. The two most important valves for controlling venous hydrostatic pressure are those of the proximal superficial femoral vein and the distal popliteal vein. Destruction of these valves is more likely to lead to sequelae. The goal is to diagnose DVT before a thrombus either embolizes or becomes extensive enough to permanently damage these or any other valves.

Clinical diagnosis of acute DVT, without the benefit of radiographic or noninvasive techniques, has been reported to be notoriously inaccurate for years, with only about a 50% accuracy rate. However, this accuracy was probably underestimated because it was

## TABLE 88-1 Wells Scoring System for Predicting Deep Venous Thrombosis

Clinical Variable	Score*
Active cancer (ongoing treatment or active within the last 6 mo or palliative care for cancer)	I
Paralysis, paresis, or recent plaster immobilization of the lower extremities	1
Recently bedridden for 3 or more days, or major surgery within the last 12 wk requiring regional or general anesthesia	1
Localized tenderness along the distribution of the deep venous system	1
Entire leg swelling	1
Calf swelling at least 3 cm larger in circumference than that of the asymptomatic leg, measured 10 cm below the tibial tuberosity	I
Pitting edema confined to the affected leg	1
Distended collateral superficial veins (not varicosities)	1
Previously documented DVT	
Alternative diagnosis at least as likely as DVT	-2

DVT, deep venous thrombosis.

\*Scoring method: if I or less, DVT unlikely; if 2 or greater, DVT likely. From Wells PS, Owen C, Doucette S, et al: Does this patient have deep vein thrombosis? JAMA 295:199–207, 2006.

based on older studies performed on seriously ill, hospitalized patients. Since then, various scoring systems have been developed in an attempt to predict pretest likelihood of DVT in ambulatory patients. The best known and studied is the Wells scoring system, which was first proposed in 1995 and updated in 2003. Although patients in this study were ambulatory, they were seen in either the emergency department or hospital, so these data may not be as applicable to patients in a primary care clinic. However, the Wells system has since been studied in 1082 ambulatory patients presenting to 5 major academic medical centers. Of these, 495 patients were thought likely to have DVT, whereas 587 were categorized as unlikely. Diagnostic evaluation followed by 3 months of observation confirmed DVT or pulmonary embolism in 28% of those thought likely to have DVT and in only 5.5% of those deemed unlikely to have DVT (Table 88-1). Combining the Wells system with further diagnostic studies can be used to virtually exclude DVT. For instance, a negative D-dimer test result in those thought unlikely to have DVT effectively excluded DVT (<1%) during the 3-month follow-up.

## Alternatives for Diagnosis of Deep Venous Thrombosis, Their Limitations, and Evidence Supporting Their Use

- 1. Contrast venography is regarded as the gold standard for diagnosis of DVT; however, it is not without its own risks-including allergic reactions, congestive heart failure, acute renal insufficiency, and postvenography syndrome. (After venography, postvenography syndrome affects 10% to 20% of patients. Although it usually causes only transient discomfort in the calf for 24 to 48 hours, and in most cases it resolves without treatment, it may actually progress to DVT.) In addition, venography is not easily repeated, and it is usually performed only in one limb. Venography may be impossible to perform in patients with poor venous access, especially obese patients and those with severe edema or cellulitis. It may also be difficult to perform in urgent situations without proper support staff. Furthermore, contrast venography cannot be performed in 20% to 25% of patients because of previous DVT. Although a study of postmortem contrast venograms reported a sensitivity rate of 95% and a specificity rate of 97% for diagnosis of DVT, a more recent multicenter study evaluating the degree of interobserver variation questions these high sensitivities and specificities. For these reasons, as well as the fact that compression and duplex ultrasonography have become more readily available, they have basically replaced contrast venography for making the diagnosis of DVT.
- 2. Compression ultrasonographic imaging (high-frequency, B-mode, realtime) has limitations in obese and asymptomatic postoperative patients. Ultrasonography's ability to visualize the venous system above the inguinal ligament (i.e., pelvic, iliac veins) or distal to the popliteal vein is also limited. That said, for symptomatic proximal DVT, sensitivities ranging from 93% to 100% and specificities ranging from 97% to 100% have been reported since the 1980s (Appelman and colleagues, 1987; Vogel and colleagues, 1987; Cronan and colleagues, 1987; Lensing and colleagues, 1989). Compression ultrasonography is less operator dependent than duplex scanning, and this may explain why it is the most common technique used in large urgent-emergent care centers and after hours in hospitals. Because it is a less expensive technique, many centers have developed algorithms for its use; they either use compression ultrasonography alone in low-risk patients or use compression ultrasonography as a screen to determine whether a duplex scan is needed. Although approximately 10% of isolated calf DVTs will be missed with compression ultrasonography, calf DVT by itself is not life-threatening and may only need to be followed to exclude proximal progression. Benefits of compression ultrasonography include the ability actually to visualize the veins, valves, and thrombus. Compression ultrasonography may be necessary in special cases in which (other than

- obese or asymptomatic postoperative patients) impedence plethysmography (IPG) has unclear results or limitations. Compression ultrasonography is also usually performed during duplex scanning.
- 3. Duplex ultrasonographic scanning combines velocity measurements using Doppler technology with ultrasonographic imaging. Duplex scanning may be used to confirm findings from compression ultrasonography. Duplex scanning is accurate and reproducible, and compared with venography, its sensitivity and specificity for DVT are more than 90%. Both the positive and negative predictive values for DVT are in the 90% to 95% range. Studies have shown that color enhancement of the Doppler velocities also improves accuracy in areas where compression may be difficult, such as at the inguinal ligament, the adductor canal, or in the calf veins. It may also be used to determine the patency of the pelvic and iliac veins and the inferior vena cava.
- 4. Electrical impedance plethysmography was previously the most extensively studied and commonly used noninvasive technique. It remains the least expensive and least operator-dependent alternative to venography. IPG provides a functional evaluation of the venous system for outflow obstruction. Compared with contrast venography, a sensitivity of 92% and a specificity of 95% were reported for IPG from studies in the 1990s. However, the range for sensitivity dropped to 66% in one study. High falsepositive rates are found in the presence of certain conditions (e.g., obesity, congestive heart failure, external venous compression from gravid uterus in pregnancy) and chronic DVT. IPG is inaccurate in the diagnosis of thrombi in calf veins, profunda femoris, or internal iliac veins. It is also limited for diagnosing nonoccluding DVT, asymptomatic or moderately symptomatic DVT, and, therefore, postoperative DVT. IPG is limited for diagnosing clots in paired veins or determining the progression of disease. For these situations, duplex or color Doppler imaging has mostly replaced IPG. That said, a number of prospective studies (Hull and colleagues, 1985; Huisman and colleagues, 1986; Heijboer and colleagues, 1993) have demonstrated that serial negative IPGs are sufficiently sensitive to justify withholding anticoagulation, even in symptomatic patients.
- 5. Hand-held (pocket) Doppler (with or without recorded velocities) can be used to assess venous function. Pooled data from several studies found an overall sensitivity of 84% and specificity of 88% for detection of lower extremity DVT in symptomatic outpatients. However, individual studies report sensitivities ranging from 31% to 100% and specificities ranging from 59% to 100%, thereby indicating the shortcoming of this technique and the fact that it is very operator dependent (Turnbull and Dymowski, 1989). Consequently, hand-held Doppler is probably most useful when combined with another study such as compression ultrasonography or IPG, and was therefore included in the protocols of many of the original noninvasive venous studies. When combined with compression ultrasonography or IPG, hand-held Doppler can add information about the calf veins.
- 6. D-dimer, a degradation product of cross-linked fibrin, is usually elevated in patients with DVT. After determining pretest likelihood, the results of a high-sensitivity D-dimer assay can be used in place of IPG, ultrasonography, or duplex scanning in patients unlikely to have DVT and is especially useful in symptomatic patients with a suspected first episode of DVT. It can also be checked in addition to IPG, ultrasonography, or duplex scanning. A D-dimer test is most effective in excluding DVT in outpatients because hospitalized patients frequently have other conditions that cause an elevated result (i.e., false positives). Increasing age also increases the likelihood of false-positive results. Although there are at least seven commercial assays available, the enzymelinked immunosorbent (ELISA) technique is considered a high-sensitivity test. From a recent meta-analysis (Wells and colleagues, 2006), a negative high-sensitivity D-dimer test combined with a low-probability score (pretest likelihood) resulted in a 0.1% likelihood of DVT during 3-month follow-up without

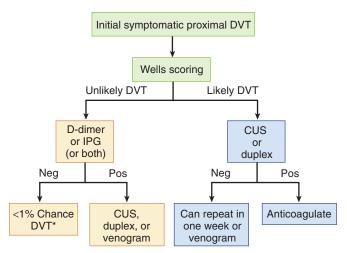

Figure 88-2 Algorithm for incorporating Wells scoring system into testing for deep venous thrombosis (DVT). (1) If DVT is unlikely (see Table 88-1) and the moderate or high-sensitivity D-dimer test (or impedence plethysmography [IPG], or both) result is negative, no further testing is required. (2) Symptomatic patients with an abnormal compression ultrasonography (CUS) or duplex study result can be treated without any further testing, or (3) if the patient has a negative CUS or duplex study result, yet DVT is likely, options include venography or serial CUS or duplex studies (i.e., repeat in I week). This algorithm provides a safe and cost-effective manner of excluding DVT. \*Because this algorithm has not been studied prospectively and there is some subjectivity in using the Wells scoring system, some clinicians will always perform another noninvasive test before excluding DVT.

using ultrasonography. Although semiquantitative slide agglutination assays are probably not accurate enough to use for exclusion of DVT (low sensitivity), newer quantitative agglutination methods (moderate sensitivity) have increased the accuracy to acceptable levels (<0.5% during 3-month follow-up) in patients unlikely to have DVT by the Wells scoring system. Likewise, bedside assays that use whole blood are also now available and are considered to be of moderate sensitivity and useful when combined with the Wells scoring system (Fig. 88-2).

7. Radionuclide scintigraphy or magnetic resonance venography (MRV) may be useful in selected patients. Scintigraphy uses radiolabeled albumin or tagged red blood cells as the contrast for venography. However, it may be unreliable in the calf and not helpful in those with previous DVT. Radiolabeled autologous platelets or peptides can also be used to detect active thrombus formation. These techniques may be helpful in symptomatic patients with a previous history of DVT. MRV is particularly useful in the diagnosis of portal, inferior vena caval, pelvic vein, or calf vein DVT. However, MRV is highly operator dependent, expensive, and not always available in urgent situations. It should probably be reserved for cases in which scintigraphy is contraindicated. Both radionuclide scintigraphy and MRV are beyond the scope of this textbook.

#### **Indications**

#### Nongravid

- Verification of clinically suspected acute DVT. (This may require serial studies if calf thrombosis is suspected, and especially if IPG or compression ultrasonography is the diagnostic study used. Neither of these techniques is highly sensitive for calf thrombosis and serial studies are recommended to monitor for more proximal progression of a thrombus, which will occur in approximately 25% of patients. Asymptomatic calf vein thrombosis seems to progress proximally as frequently as that in symptomatic patients.)
- Diagnosis of recurrent DVT.
- Evaluation before discontinuation of anticoagulation for DVT.
   (E.g., IPG has been used to verify collateral flow or lysis of the thrombus by repeating every 4 to 6 weeks until the results return

to normal. However, it should be noted that insurers often reimburse only for symptomatic patients.)

- Venous evaluation of patient with pulmonary embolism.
- Preoperative study before saphenous vein stripping.
- Preoperative study before venous sclerotherapy.
- Venous insufficiency.

#### Gravio

 Gravid patients with superficial venous thrombosis should be evaluated thoroughly because up to 17% will also have DVT. DVT in a gravid patient places her at very high risk of pulmonary embolism. (One review of maternal deaths revealed that pulmonary embolism was the second leading cause of death.)

#### **Considerations**

- Unilateral or unexplained edema of the lower extremity, especially if associated with pain in area
- Screening of certain high-risk patients (e.g., postoperative, especially with multiple risk factors; see Table 88-1)
- Suspected pulmonary embolus (in combination with either a multidetector CT pulmonary angiogram or a V/Q scan)

#### COMPRESSION ULTRASONOGRAPHIC SCANNING

Real-time, B-mode ultrasonography in the higher frequency ranges (5 to 10 MHz) allows direct "visualization" (imaging) of the venous system, and it allows the technician or clinician to search for a thrombus. Sound waves are best transmitted in fluid; therefore, large veins and arteries are easily visualized with the proper probe and adequate acoustic gel interface. Arteries are differentiated from veins by their thicker walls and pulsatile nature. They are also not as easily compressed when pressure is applied on the leg with the probe. In addition, arteries do not engorge with a Valsalva maneuver or vary with respiration.

Compression ultrasonography is currently the most widely used noninvasive test for diagnosis of DVT. In some situations, such as after 5:00 PM in some emergency departments, compression ultrasonography is the only diagnostic modality available. Studies of such situations have indicated that accuracy of diagnosis of DVT by compression ultrasonography approaches that of venography.

#### **Personnel and Equipment**

- A clinician or technician familiar with venous anatomy (Fig. 88-3) as well as ultrasonographic technology
- 5- to 10-MHz probe (transducer) and scanner (2- to 3.5-MHz probe in obese patients)
- Acoustic gel

#### **Technique**

- Place the patient in the supine position with the lower extremities lowered about 20 or 30 degrees (reverse Trendelenburg), slightly separated and externally rotated. This position increases the fluid volume in the veins and facilitates scanning. The patient should be relaxed, comfortable, and bearing most of the weight on the contralateral side to avoid venous compression by tense muscles.
- 2. Apply ample acoustic gel. With the probe perpendicular to the vessel and beginning at the groin, scan the common femoral vein, the saphenofemoral junction (the most common location for a thrombus to extend from superficial to deep veins), and then the superficial femoral vein. Scan distally in the longitudinal and transverse dimensions. Longitudinal scanning is usually used to locate and follow the vein, whereas transverse scanning is used to check for compressibility. Have the patient perform a Valsalva maneuver, which should expand the veins, enhancing visualization as far distal as the popliteal veins. Echogenic matter (which appears white) within the vessels should be studied carefully to exclude a possible thrombus. Presence or absence of thrombus should be recorded. Partially obstructing thrombi may be confused with scarred, thickened venous walls; therefore, it is important to record and comment about wall thickness. If a thrombus is found in the femoral veins, attempt to scan the iliac veins and inferior vena cava for the presence of additional thrombi.
- 3. If no thrombus is visualized, turn the probe transversely and apply gentle pressure to compress the vessel walls. Compressions should be made every 3 to 5 cm, progressing distally. If the vein is not compressible, continue to apply increasing pressure until the diameter of the adjacent artery is reduced slightly. At this pressure, if the vein is not compressible, an early thrombus is preventing compression; it may not have become organized or

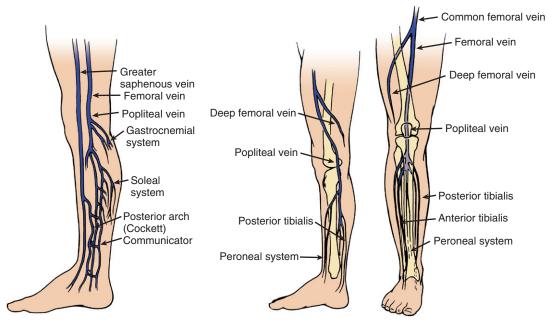

Figure 88-3 Venous system of the lower extremity.

- dense enough to be visualized or cause echoes. Compressibility of the vein walls (or lack thereof) should be recorded.
- 4. Proceed distally and continue scanning vessels in the longitudinal and transverse dimensions to the mid-medial and then the distal thigh. In the distal thigh, fascial planes at the adductor hiatus (Hunter's canal) may obscure the superficial femoral vein.
- 5. Next, scan the popliteal vein either with the patient in this position or by rotating the patient to a prone position with the knees flexed 20 or 30 degrees. A pillow placed under the feet may facilitate this position and enhance patient comfort.
- 6. In about 30% of patients, infrapopliteal vessels can be scanned, with the anterior and posterior tibial veins visualized more easily than the peroneal veins. Sitting the patient up and allowing his or her legs to dangle over the edge of the bed may enhance imaging of the calf veins.
- 7. Valve thickness and motion should be recorded when observed.
- Vein response to a Valsalva maneuver and deep inspiration should be recorded at the level of the common femoral, superficial femoral, and popliteal veins.

#### Interpretation

- Visualization of an intraluminal thrombus is diagnostic. A thrombus is further confirmed when a Valsalva maneuver produces minimal changes in vein diameter and the vessel wall is incompressible. Early studies indicate that these diagnostic criteria are superior to all other techniques, except venography, for diagnosing DVT. In a symptomatic patient, treatment (anticoagulation) can be initiated with the visualization of a thrombus alone.
- A probable positive study is one in which the veins are incompressible or do not distend with a Valsalva maneuver. Consider duplex scanning for confirmation if a thrombus is not visualized during compression ultrasonography. The accuracy and outcomes of duplex scanning have been studied extensively, and it produces diagnostic results similar to venography in cases in which a thrombus is not visualized.
- Occasionally, an acute thrombus can be differentiated from a chronic thrombus. Acute thrombi can have low-level echoes and tend to have a homogeneous texture, can be free-floating, and are somewhat compressible. The vein is often dilated. A chronic thrombus increases in echogenicity and decreases in size. With a chronic thrombus, although the vein is usually back to its normal diameter (i.e., the same diameter as the corresponding vein on the contralateral side), it will still contain an echogenic clot partially obstructing the lumen. Lateral veins will often form alongside. Chronic thrombi usually are not compressible, have heterogeneous echogenicity, and are firmly attached to the walls.
- Increased wall thickness, especially compared with veins of the contralateral extremity, can be due to previous or chronic DVT or to a partially obstructing thrombus. All of these possibilities should be strongly considered in a symptomatic patient because all of these scenarios also place the patient at risk for DVT.
- At least one published study indicates safety in withholding treatment with a negative compression ultrasonographic study result. This result should be weighed against the pretest likelihood of DVT and availability of duplex scanning. However, even in patients likely to have DVT by the Wells scoring system, two negative compression ultrasonographic studies, performed a week apart, reduces the risk of DVT to less than 1% (see Fig. 88.2)
- Although superficial thrombophlebitis is not life-threatening, patients with saphenous vein phlebitis should be scanned very thoroughly; one prospective study found 33% of patients with a thrombus in the above-knee segment of the greater saphenous vein had a documented episode of pulmonary embolism. Likewise, although isolated calf vein thrombosis is not life-threatening, it propagates proximally into the popliteal vein and thigh in

- approximately 25% of patients, so there is value in repeating the scan in 1 week. If the result is negative, it reduces the risk of proximal DVT to less than 2%. The risk of proximal propagation is apparently as high in asymptomatic calf vein thrombosis as in symptomatic.
- Because of the lack of a validated clinical model, making the diagnosis of recurrent DVT can be challenging. The diagnosis is easier if it occurs in a new location or in the contralateral extremity. However, if it recurs in the same venous segment of prior DVT, it requires comparison with a prior study. Clearly, a newly noncompressible segment confirms recurrent DVT. Certain experts consider an increase of greater than 2 mm in the compressed diameter (or 4 mm in the uncompressed diameter) of the previously thrombosed venous segment to be diagnostic for recurrent DVT. An extension of the length of the thrombus by 9 mm is also considered recurrent DVT by most sonographers. Conversely, fully compressible deep veins or no significant increase in diameter excludes recurrent DVT.

#### **DUPLEX SCANNING**

Duplex scanning adds another parameter—venous blood velocity—to the data obtained from a compression ultrasonographic study. With duplex scanning, Doppler technology is incorporated into the probe of an ultrasonographic scanner. The drawbacks to duplex scanning include its cost to the patient (averaging \$300 to \$600 per study), the cost and nonportability of equipment, the time required for a complete examination, and the experience required for the technician or clinician to perform and interpret the study. In many centers, it is not available at all hours or in urgent situations. As with compression ultrasonography, the ability to study the venous system above the inguinal ligament, and occasionally the superficial femoral and tibial veins at the adductor hiatus, is poor compared with IPG.

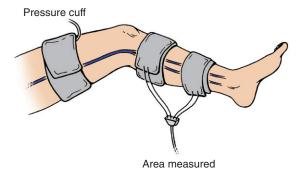

Duplex scanning has advantages over compression ultrasonography in areas where the vein cannot be compressed because of physical restrictions, such as with smaller vessels (e.g., infrapopliteal). With duplex scanning, other measurable or demonstrable parameters of venous function can be evaluated if a suspected thrombus is not clearly visualized with compression ultrasonography.

#### **Technique**

The technique of duplex scanning is the same as for compression ultrasonography, except that most of the velocity data are gathered with the probe turned longitudinally along the vein. Duplex scanning allows the evaluation of venous physiologic parameters, and there are three additional criteria for a positive result: (1) the absence of phasicity (i.e., variation) during quiet respiration, (2) the absence of spontaneous blood flow, and (3) the absence of augmentation of flow when the limb is compressed distal to the site of probe placement. The effect of a Valsalva maneuver should also be observed (e.g., should reduce venous flow to the heart). Even with a thrombus that is clearly visualized, confirmation by an alteration of these four factors can be comforting before anticoagulation therapy is initiated. In addition, valve function can be assessed; functional valves should not allow augmentation of reverse flow with proximal compression. The extent of valve function at the level of the common femoral, femoral, and popliteal veins should be routinely recorded. They should also be evaluated and recorded as far distally as possible.

#### Interpretation

Treatment decisions in most large centers are based on duplex scans alone. Occasionally, venography and duplex results differ. If clearly abnormal findings on a duplex scan are contradicted by normal findings on venography, the disparity may be due to the presence of a duplicate vein (up to 20% of patients), which may

**Figure 88-4** For impedance plethysmography testing, elevate the leg 25 to 30 degrees. Apply electrodes around the calf and place a pressure cuff around the thigh.

appear normal on venography despite the presence of a thrombus in the other vein. Also, thrombosis of a superficial femoral or popliteal vein can be missed by a venogram. Therefore, for a patient with a normal venogram despite significant symptoms, and a clearly abnormal duplex scan, treatment is not out of the question.

#### **ELECTRICAL IMPEDANCE PLETHYSMOGRAPHY**

Various plethysmography techniques are available to study a change in physical function as a result of a change in volume (e.g., strain gauge, air, IPG). Electrical IPG records the impedance (the inverse of conductivity) of the lower extremity as the blood volume varies. When venous return is restricted in the lower extremity by a cuff, venous volume in the lower extremity increases. Because blood is a good conductor of electricity, conductivity in the lower extremity also increases (i.e., resistance or impedance decreases). This is evaluated by administering a weak electrical current that is imperceptible to the patient, and then measuring the current's strength after it passes through the area. When the cuff is released, conductivity should rapidly decrease if the deep venous system is patent. In patients with a thrombus, the rate of change of electrical conductivity is reduced, especially if the thrombus is in the popliteal or more proximal vein. IPG has been proven to be safe, painless, reliable, and cost effective (cost to the patient is about the same as for an electrocardiogram, usually \$50 to \$100).

#### **Relative Contraindications**

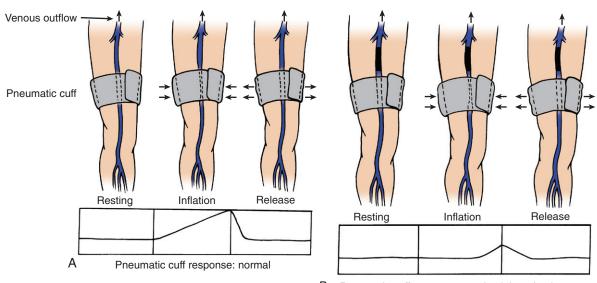

- Patients with risk of false-positive result (e.g., patient with significant pain [involuntary muscle restriction], full bladder [especially elderly patients] or the inability to relax [involuntary muscle restriction], congestive heart failure [elevated central venous pressure], external vein occlusion [pregnancy, popliteal cyst or mass], obesity, or chronic DVT). In these patients, the risk of a false-positive result is increased and initiation of anticoagulation should be weighed against the risks of waiting for the availability of another, more accurate venous study.
- Patients who are unable to remain supine, such as those with severe orthopnea.

#### Personnel and Equipment

- A clinician or technician trained to perform and record IPG
- A clinician trained to interpret IPG
- IPG recorder
- Appropriate 8-inch cuff and electrodes

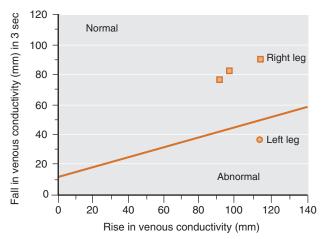

#### **Technique**

- 1. Place the patient in the supine position, with the leg to be examined elevated 25 to 30 degrees (Fig. 88-4). This can be accomplished by placing a pillow under the calf and heel. All tight garments should be removed, and the leg to be studied should be well exposed. To relax the patient, the leg is allowed to rotate externally at the hip. The knee is slightly flexed—10 to 20 degrees—to prevent compression of the popliteal vein.
- 2. Place an 8-inch-wide pneumatic cuff around the thigh and place electrodes circumferentially around the calf.
- After the instrument has been electrically balanced and a stable baseline has been obtained, inflate the cuff to the manufacturer's specification, which is usually 50 mm Hg. This blocks the venous outflow but does not impair arterial inflow.
- 4. After the cuff has been inflated for 2 minutes and the pressure tracing has reached a stable plateau, suddenly release the pressure in the compression cuff.
- 5. The total rise of the IPG tracing during cuff occlusion and the fall during the first 3 seconds of deflation are now plotted on a two-way graph (Fig. 88-5 shows normal and abnormal IPG tracings, and Fig. 88-6 shows plotting).

B Pneumatic cuff response: proximal thrombosis

Figure 88-5 Normal (A) and abnormal (B) impedance plethysmography tracings.

**Figure 88-6** Typical result of impedance plethysmography. This reading suggests deep venous obstruction in the left leg, with normal venous function in the right leg.

#### Interpretation and Sources of Error

Overall, the major shortcoming of IPG is a false-positive rate of approximately 5%. Sensitivity increases in the symptomatic patient and is reduced during evaluation for silent proximal thrombosis, such as with postoperative screening. The error rate can be minimized by a clinician with experience who takes into consideration the following factors:

- Positive predictive accuracy is improved for those with a high pretest likelihood of DVT (see Table 88-1).
- If the first result falls below the discriminant line, it is not necessarily abnormal. With repeated testing, the values may fall above the discriminant line, where they are considered normal. In the presence of true outflow obstruction, the result remains fixed. To improve the accuracy of IPG, a five-test sequence can be used with occlusion times of 45, 45, 120, 45, and 120 seconds.
- The closer the result falls to the discriminant line on either side, the more likely that it is abnormal. Such test results (close to the line) should be confirmed with either venography or duplex scanning.
- Some experts suggest that if abnormal results are found with both lower extremities, they are likely false-positive results; therefore, the patient should be evaluated further with another technique.
- Excessive tightness of the cuff, particularly in obese patients, may cause tension on the skin during cuff occlusion and thus a falsepositive result.
- Any systemic disease limiting arterial inflow or venous outflow will interfere with results.

#### HAND-HELD VENOUS DOPPLER

Hand-held Doppler studies (without imaging) can be used to qualitatively assess the venous system. The hand-held Doppler probe translates the velocity of venous blood into an audible signal or onto a chart recorder. Velocities are evaluated while the patient undergoes various maneuvers. This technology has not been studied as extensively as IPG or duplex scanning. Advantages to hand-held Doppler studies include inexpensive and, in most cases, more portable equipment. However, the safety of withholding anticoagulant treatment in patients with normal hand-held Doppler results has never been evaluated formally. For anyone performing noninvasive venous studies, a working knowledge of this technique is important to understand basic venous physiology.

#### Indications

Practical indications are slightly different than those previously discussed; for example, hand-held Dopplers may be used alone when other diagnostic methods are unavailable to confirm proximal DVT in a symptomatic patient, or they may be used to diagnose postphlebitic syndrome. This technique can also be used to screen patients for determining whether duplex scanning or IPG is indicated, especially if those studies are not readily available. If the screening test is positive, the additional cost or effort of obtaining a duplex or IPG study may be warranted. A hand-held Doppler is more reliable than IPG for the diagnosis of DVT in patients with severe arterial insufficiency or with a leg in traction. Used alone, a hand-held Doppler provides mainly qualitative evidence of venous function.

#### **Relative Contraindications**

Obese patients and patients with massive leg swelling may be difficult to study.

#### Personnel and Equipment

- A clinician or technician familiar with venous anatomy and Doppler ultrasonographic technology. (Because the vein cannot be visualized with this technique, a better knowledge of anatomy is required than with ultrasonography [see Fig. 88-3]. Experience significantly increases the accuracy of this examination.)
- 5- to 10-MHz hand-held Doppler with audio. It can often be used for listening to fetal heart tones as well.
- Acoustic gel.

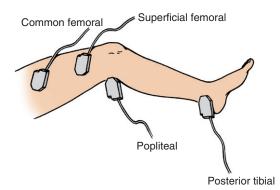

#### **Technique**

- 1. Prepare the room and patient. The room temperature should be warmer than 70° F to prevent vasoconstriction. Place the patient in the supine position with the head slightly elevated. All tight garments should be removed and the leg well exposed (tight-fitting garments may interfere with venous return). The leg should be slightly abducted, externally rotated, and slightly flexed at the knee. It should also be relaxed to prevent compression of the deep veins. Support the knee with a pillow for better muscle relaxation.
- 2. Locate the common femoral vein by first finding the artery and then moving the probe medially until the characteristic venous flow or tone is found. The best tone is usually obtained with the probe angled toward the heart (in the direction of venous flow). Use minimal probe pressure to keep from compressing the vein. Arterial flow is characterized by a high-pitched, usually abrupt, tone. Venous flow is usually lower pitched and more continuous.
- 3. Evaluate the patient with the Doppler from the level of the common femoral vein distally to the superficial femoral, popliteal, and posterior tibial veins (Fig. 88-7). When the level of the popliteal vein is reached, the patient may be turned to a prone position with knees slightly flexed. Rest the patient's feet on two pillows.
- 4. Compare the sound or tracing from one leg with that of the other leg at each level of the examination and record the results.

#### Interpretation

Four characteristics describe normal venous flow (physiology):

- It is patent if flow is heard at the anatomic level of the vein.
- It is spontaneous if it can be heard at all levels of the vein.
- It varies with respiration, or is phasic.
- It is augmented by distal compression of the limb or by release of proximal compression.

**Figure 88-7** Doppler sonographic examination. The patient is supine with the head slightly elevated. Examine the common femoral, superficial femoral, popliteal, and posterior tibial veins sequentially.

#### **Patent**

Rarely does the flow completely disappear with DVT because some flow is usually preserved around a thrombus or through collateral vessels. Differences between one side and the other may be more important, and DVT is frequently associated with a continuous, high-pitched signal. A pulsatile tone that varies with the cardiac cycle is not normal and indicates increased venous pressure.

#### **Spontaneous**

Deep venous thrombosis causes loss of spontaneous flow. Other causes of loss of spontaneity include anything leading to vasoconstriction. As previously stated, low ambient room temperature or patient anxiety can cause vasoconstriction. The posterior tibial vein may not have a spontaneous signal in normal individuals. Spontaneity is usually found when venous flow is phasic.

#### Phasic

This characteristic variation of flow with respiration may be lost with DVT. With normal veins, a Valsalva maneuver should decrease the signal, whereas a deep breath should augment the signal.

#### **Augmented**

Firm, gentle compression of the limb for a few seconds distal to the vein should cause augmentation of the flow. Release of proximal compression should also result in augmentation. DVT causes a more abrupt and shorter augmentation—if augmentation remains present at all—compared with that of a normal leg. Presence of augmentation provides support that the vein is patent. Reverse augmentation produced by proximal compression or after releasing distal compression indicates valvular incompetence.

False-negative results may occur in patients with incomplete venous obstruction by thrombi and false-positive results may be caused by extrinsic venous compression. When treatment decisions are made, the fact that no outcome studies are available using hand-held Doppler alone must be weighed against the availability of compression ultrasonography, duplex, IPG, or contrast studies. Abnormal Doppler results are frequently confirmed with another technique. It should be noted that portable hand-held Doppler equipment, similar to various types of plethysmography equipment (other than electrical IPG), is relatively inexpensive. Either can be used alone, but in combination they may complement each other and provide additional types of quantitative data. These supplementary studies may be helpful to the clinician when determining which patients need further evaluation.

#### **NONINVASIVE ARTERIAL STUDIES**

Peripheral artery disease (PAD) affects 29% of patients in a primary care clinician's office who are older than 70 years of age (or older than 50 years of age with a history of diabetes or smoking). Although only a small proportion of individuals with PAD and intermittent

claudication develop skin breakdown or limb loss, the associated pain and disability from PAD often restrict ambulation. The restriction of ambulation not only interferes with the quality of life, it may interfere with the ability to prevent coronary artery disease (CAD) with exercise. PAD can progress to pain at rest, ulceration, and gangrene. Men are affected more frequently than women. Diabetic patients and smokers develop this disease more frequently and at an earlier age, and the prognosis is grave in diabetic patients because PAD almost always progresses. Diabetic patients also have a greater incidence of vessel involvement between the knee and ankle. Diabetic PAD is responsible for about half of all amputations.

A history of intermittent claudication and absent or diminished peripheral pulses are unreliable signs or symptoms of PAD. PAD most frequently involves the superficial femoral and popliteal arteries, followed by the distal aorta and iliac arteries, in order of decreasing frequency. The absence of a posterior tibial pulse is a more useful finding on examination than the absence of a dorsalis pedis pulse because 10% to 15% of persons have congenitally absent dorsalis pedis pulses. However, neither finding is very accurate.

Multiple noninvasive techniques are available for the diagnosis of lower extremity PAD. A comprehensive history and physical examination and a combination of at least two noninvasive tests should be performed to both confirm the diagnosis and determine the location of the lesion. If the location of a hemodynamically significant lesion is known, the risks associated with tests involving contrast dye can be minimized; this knowledge can also guide the radiologist's, cardiologist's, or surgeon's approach for optimal contrast visualization. Different and sometimes more useful information can be gained from noninvasive studies than with contrast studies; as a result, some radiologists/cardiologists/surgeons operate without subjecting the patient to preoperative contrast studies. Although it can be very operator dependent for a small artery (e.g., popliteal artery), the accuracy of MR or CT angiography is similar to that of a contrast study. Contrast studies may also be avoided if noninvasive studies fail to demonstrate a hemodynamically significant lesion consistent with the patient's symptoms.

NOTE: The clinician must always consider the possibility of cardiac and cerebrovascular disease in patients with PAD. Intermittent claudication is often the first sign or symptom of generalized atherosclerosis, and these patients most frequently succumb to myocardial infarction or stroke. National guidelines consider PAD a cardiovascular risk equivalent, meaning the patient with PAD has at least as high a risk of a myocardial infarction over the next decade (i.e., 20%, if not higher) as a patient who has previously experienced a myocardial infarction. Using routine coronary angiography in patients with claudication, CAD was identified in 90% of patients and severe CAD in 28% of patients. The Framingham Study demonstrated a 10% risk of fatal stroke in patients with claudication. Therefore, treatment should be targeted to prevent myocardial infarction and stroke as much as to prevent complications of PAD.

Regarding screening, although noninvasive studies are more accurate than physical examination, the literature does not demonstrate a benefit to early detection of PAD. Even though noninvasive diagnosis of PAD may be one of the easiest methods to diagnose generalized atherosclerosis, additional data are needed before non-invasive testing should be considered for routine screening.

#### **Risk Factors**

- Older age
- Male
- Diabetes
- Cigarette smoking
- Hypertension (greater risk factor for women)
- Hyperlipidemia (not a consistent independent risk factor for claudication)
- Family history of PAD (although a risk factor for CAD, this may not be a risk factor for claudication)

 Homocystinemia, hyperfibrinogenemia, hypercoagulable states (probable risk factors)

#### **Indications (Especially in Diabetic Patients)**

- Intermittent claudication
- Nonhealing foot ulcer
- · Exertional leg pain of unknown etiology
- Possible trauma to an artery

#### **Considerations**

- To screen before lower extremity surgery in a diabetic patient
- To screen patients with neuropathy who may have ischemia without symptoms (numbness from neuropathy)
- To follow a patient after reconstructive arterial surgery or percutaneous intervention (angioplasty or stent) or for whom nonoperative therapy is selected
- It has been said that an experienced clinician can diagnose PAD in most patients by using the history and physical examination alone. However, many clinicians who evaluate patients with extremity pain are neither experienced nor current in the management of vascular disease. Noninvasive studies provide an objective, definitive diagnosis so that clinicians can either rule in PAD or search for another cause for the symptoms.

#### **SEGMENTAL PRESSURE MEASUREMENT**

The segmental pressure study is the most generally accepted and widely applied noninvasive arterial test. Segmental pressures are often evaluated as the initial test for a possible arterial abnormality.

#### Personnel and Equipment

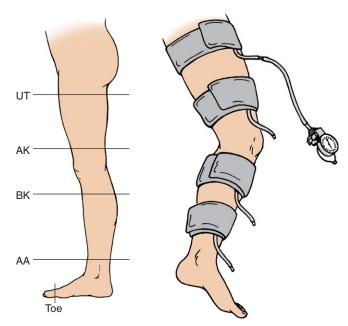

- A clinician or technician familiar with arterial anatomy of the foot and Doppler ultrasonographic technology
- 5- to 10-MHz hand-held Doppler probe (transducer) with audio
- Acoustic gel
- Aneroid (gauge) manometer
- Four cuffs for each leg (they can be of the same diameter; if eight are available, study time is considerably reduced)

With arterial stenosis, and especially with collateral flow, arterial resistance is significantly increased. This increased resistance leads to a large or asymmetric drop in arterial blood pressure over the particular arterial segment with obstruction. The brachial pressure can also be used as a standardized reference for the pressures of the lower extremity. At a minimum, brachial pressure should always be recorded along with its ratio to the pressure at the ankle (i.e., ankle—brachial index [ABI]).

When using a pressure gauge (aneroid as opposed to mercury manometer), artifact is not a concern if the same gauge is used throughout the study (ratios and gradients are the values obtained rather than absolute blood pressure measurements). Likewise, the same cuff widths can be used throughout the lower extremities without concern for cuff artifact. (Interpretation has taken cuff artifact into account.) In most cases this technique produces a high-thigh systolic pressure greater than the brachial artery pressure, which is acceptable for calculating ratios.

#### **Technique**

- 1. With the patient in the supine position, measure systolic pressures in both arms and record them.
- 2. On one lower limb apply four segmental cuffs (Fig. 88-8). The systolic values recorded refer to the cuff level rather than the artery studied.
- Using the hand-held Doppler, evaluate the three major arteries of the foot (dorsalis pedis, posterior tibial, and peroneal) for the strongest signal. Use this artery for the remainder of the study.

**Figure 88-8** Segmental arterial pressure measurement. Cuff positions: AA, above ankle; AK, above knee; BK, below knee; UT, upper thigh.

When determining pressures, hold the Doppler probe consistently over the artery at the angle and in the direction that produces the strongest signal.

- 4. Using the same pressure gauge throughout, attach it to a cuff and inflate the cuff until the Doppler signal in the foot disappears.
- 5. Deflate the cuff slowly until the first signal is audible in the foot and record this systolic pressure for that cuff level.
- Sequentially inflate and deflate and record the systolic pressures for each cuff level. Repeat at the same four levels on the other lower extremity.
- 7. Calculate the ABI, which is the highest ankle systolic pressure divided by the highest brachial systolic pressure.

#### **Sources of Error**

Most errors arise when the examiner moves the probe off the artery while inflating the cuff. One limitation of this technique is that, even though it is fairly sensitive for diagnosing PAD, it is not as helpful for localizing lesions.

Vessel calcification, such as that found in patients with diabetes and chronic renal failure, may lead to an arterial segment that is compressible only at very high pressures (e.g., >300 mm Hg) and may produce unusual results. In fact, segmental pressures may appear to follow a reverse gradient. Suspect vessel calcification when the ABI is higher than 1.4.

With an ABI less than 1.0, always consider the possibility of an obstructed aorta or bilaterally obstructed iliac arteries. Because of cuff artifact, high-thigh pressures may be greater than brachial pressures and mask aortic or iliac obstruction.

With an abnormal study result, consider comparing the systolic pressures in all the arteries of the foot. This prevents the artifact that might be produced if there is localized obstruction of just one pedal artery.

#### Interpretation

The single best method of quantitative screening for PAD is an ABI determined by Doppler ultrasonography. Normally, the ankle pressure is equal to or slightly greater than the arm pressure. An ABI less than 0.95 is abnormal. Typically, patients with rest claudication or gangrene have ABIs less than 0.5, which often indicates multisegmental disease. Patients with intermittent claudication usually

have ABIs between 0.5 and 0.9, generally associated with single-segment disease.

During a follow-up evaluation, a change in the ABI of more than 0.15 is considered clinically significant. A decrease in this amount usually indicates disease progression or a problem with a reconstructive procedure. An increase suggests improvement in circulation resulting from the development of collaterals. There is no current consensus on how often studies should be repeated.

A high-thigh pressure less than the arm pressure, any pressure drop of 30 mm Hg or more from one segment to the next, or a difference of 30 mm Hg or more between extremities at the same segmental level signifies a probable obstruction in that segment. Some asymmetry of results in the lower extremities is normal. Remember that pressure drops may represent the sum of more than one lesion.

NOTE: Many clinicians use the ABI alone to screen for PAD, and studies have verified its value for use in this manner (Hirsch and colleagues, 2001); however, it requires staff time to perform, document, and interpret the findings. This must be weighed against the fact that although Medicare and other insurers now reimburse for this procedure (CPT-93922), many insurers reimburse only for symptomatic patients. Beckman and colleagues (2006) recently demonstrated that an automatic blood pressure cuff (using the oscillatory technique) can be used to check ABI (and save time), with a sensitivity of 88%, specificity of 85%, and a negative predictive value of 96%. If normal, a screening ABI performed in this manner probably does not need to be repeated more than once every 5 years.

#### **WAVEFORM ANALYSIS**

Velocity or pulse volume waveform analysis is indicated whenever there is an abnormal ABI or segmental pressure study. These studies can confirm each other and assist in localization of the obstruction.

#### **VELOCITY WAVEFORM ANALYSIS**

#### **Personnel and Equipment**

- A clinician or technician familiar with arterial anatomy of the lower extremity and Doppler ultrasonographic technology
- 5- to 10-MHz probe (transducer) with audio and chart recorder
- Acoustic gel

**NOTE:** The same equipment can often be used for venous Doppler studies.

#### **Technique**

- Prepare the room and patient. The room temperature should be greater than 70° F to prevent vasoconstriction. The patient should rest in the supine position for at least 10 minutes. The leg should be well exposed, slightly abducted, externally rotated, and slightly flexed at the knee. Supporting the knee with a pillow may increase patient comfort.
- Beginning at the common femoral artery, apply acoustic gel and auscultate with the probe for maximal tone and amplitude on the recorder. The best tone is usually obtained with the probe pointed

- away from the heart in the direction of arterial flow. Arterial flow is characterized by a high-pitched, usually abrupt tone. This should be differentiated from the sound of venous flow, which is usually lower pitched and more continuous.
- 3. Obtain tracings from common femoral, popliteal, and posterior tibial arteries. For the popliteal arteries, the patient may be turned to a prone position with knees slightly flexed and feet resting on two pillows if this position is more comfortable.
- Compare the sound and tracing from one leg with the other leg at each level of the examination and record.

#### **Sources of Error**

- Dense objects or tissue (e.g., local excess fat, hematoma, scar tissue, or plaque on the anterior wall of the vessel) may significantly interfere with ultrasound transmission, making it more difficult to obtain a tracing.
- Prosthetic vessels are almost impossible to study.
- In severe disease, tracings may be unattainable in spite of being able to hear a tone, especially in distal extremities.
- With an incorrect probe angle, the multiphasic components of a tracing can be missed or lost.

#### Interpretation

The normal arterial velocity signal is multiphasic, characterized by one systolic and one or more diastolic components. With a directional Doppler study, the diastolic component should at first be briefly negative followed by a positively directed systolic flow component (Fig. 88-9). The diastolic component may be decreased in a vasodilated individual and increased in a vasoconstricted individual.

The arterial velocity signal produced *just proximal* to an occlusion is usually of low amplitude and short duration (Fig. 88-10A). The arterial velocity signal produced *over* a stenotic segment is characteristically high pitched with less prominent diastolic components (Fig. 88-10B). The arterial velocity signal produced *distal* to a stenotic segment usually lacks a diastolic component and has a dampened systolic signal. It is not as high pitched as the stenotic signal (Fig. 88-10C). The arterial signal *far distal* to a stenotic segment is like the poststenotic segment but is likely to have an even lower amplitude. *Collateral* signals are high pitched and nearly continuous.

To differentiate the contour of normal arterial signals from the contour of obstructed arterial signals, clinicians often describe them as "teepees" and "igloos." "Teepee" refers to the shape of the velocity tracing of a normal artery with its rapid upstroke and resultant high amplitude. The sluggish upstroke tracing with minimal amplitude, as seen with the typical postobstructed artery, might well be described as an "igloo."

A rule of thumb: the presence of a *multiphasic* Doppler signal in a distal vessel, such as that of the foot, strongly suggests that the proximal artery is normal.

#### **PULSE VOLUME WAVEFORM ANALYSIS**

Pulse volume recordings (PVRs) are less operator dependent, are not limited by calcification of the vessel walls, and are readily and rapidly obtained using the same cuffs already in place for segmental

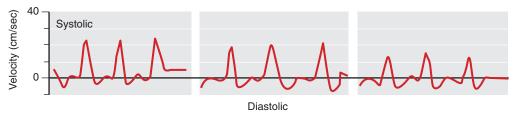

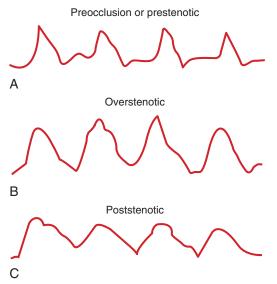

Figure 88-9 Normal arterial Doppler velocity tracings

**Figure 88-10** Examples of prestenotic (**A**), overstenotic (**B**), and post-stenotic (**C**) tracings.

pressure measurements. This is a quantitative measurement that allows reasonably accurate localization of a lesion or lesions.

#### **Personnel and Equipment**

- A clinician or technician familiar with PVR technology
- Pulse volume recorder
- Four cuffs for each leg (they can be of the same diameter; if eight are available, the study time is reduced)

#### **Technique**

- Place the patient in the supine position. Cuffs are placed in the same locations as for segmental pressure determinations and are inflated to 65 mm Hg.
- 2. Record the PVR at each level.

#### Source of Error

With severe proximal disease it may be difficult to assess the degree of distal disease because the PVRs are often flat throughout the extremity.

#### Interpretation

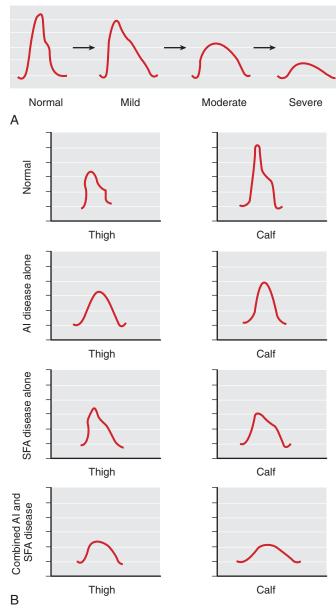

Changes in waveforms with progression of PAD are shown in Figure 88-11. First noted is the loss of the reflected diastolic wave. Next, with more progressive disease, a decrease is seen in the rate of fall of the catacrotic limb, or the downsloping portion. Finally, a further delay in the rise of the anacrotic limb, or the upsloping initial portion of the wave, is noted. With moderate to severe disease, an "igloo" is the predominant feature.

#### **OTHER STUDIES**

For the patient with a history of claudication or intermittent claudication, and yet normal vascular studies, additional testing is available.

1. Vascular treadmill stress testing is probably the most commonly used next study. Because of the cost of equipment, a referral to a vascular laboratory may be necessary. For those with a treadmill, after recording ankle systolic pressures, have the patient walk at a speed of 2 miles per hour with a 12% grade until pain

begins or 5 minutes elapses. Patients older than 50 years of age should have continuous electrocardiographic monitoring. The time it takes to induce pain is noted as the maximal walking time. Once the pain begins, or 5 minutes has elapsed, the patient is placed in a supine position and the ankle systolic pressure is again recorded. It should be recorded every minute until it returns to baseline. In healthy individuals, strenuous exercise causes a transient fall in ankle systolic pressure, which quickly returns to baseline at rest. In contrast, when a patient with PAD exercises, pain usually commences before 5 minutes and the ankle pressure falls precipitously, often to unrecordable levels. It usually does not recover for several minutes. A fall in systolic pressure of more than 20 mm Hg from baseline and a recovery time of more than 3 minutes are considered abnormal. (Note that when using the resting brachial pressure to calculate a postexercise ABI, some

**Figure 88-11 A,** Alterations seen in pulse volume waveform as arterial occlusive disease progresses from mild to moderate to severe. **B,** Various thigh and calf waveform patterns characteristic of aortoiliac and superficial femoral arterial occlusive disease. In the normal example, notice the contour of both the thigh and calf waveforms as well as the characteristic increase in amplitude of the calf pulse volume recordings. Al, aortoiliac; SFA, superficial femoral artery.

sources consider a postexercise ABI abnormal if it falls more than 20% from baseline and remains low for more than 3 minutes.) If a postexercise ABI returns to normal in 5 minutes, it suggests a single PAD lesion; delays of more than 10 minutes suggest multilevel PAD.

- Toe raises, up to 50 repetitions, have been substituted in many vascular laboratories for treadmill walking with good results, and this can be performed in the office setting.
- MRA—although sometimes a long, complex, and expensive procedure, some clinicians have replaced contrast angiography with MRA and perform contrast angiography only while they are performing a percutaneous intervention (angioplasty or stent).
- 4. Multislice CT angiography—although it requires considerable radiation and as much contrast dye as a regular angiogram, multislice CT angiography may replace percutaneous angiography.

#### **CPT/BILLING CODES**

- 93922 Noninvasive physiologic studies of upper or lower extremity arteries, single level, bilateral (e.g., ankle/ brachial indices, Doppler waveform analysis, volume plethysmography, transcutaneous oxygen tension measurement)
- 93923 Noninvasive physiologic studies of upper or lower extremity arteries, multiple levels or with provocative functional maneuvers, complete bilateral study (e.g., segmental blood pressure measurements, segmental Doppler waveform analysis, segmental volume plethysmography, segmental transcutaneous oxygen tension measurement, measurements with postural provocation tests, measurements with reactive hyperemia)
- 93924 Noninvasive physiologic studies of lower extremity arteries, at rest and following treadmill stress testing, complete bilateral study
- 93925 Duplex scan of lower extremity arteries or arterial bypass grafts, complete bilateral study
- 93926 Duplex scan of lower extremity arteries or bypass grafts, unilateral or limited study
- 93965 Noninvasive physiologic studies of extremity veins, complete bilateral study (e.g., Doppler waveform analysis with responses to compression and other maneuvers, phleborheography, impedance plethysmography)
- 93970 Duplex scan of extremity veins including responses to compression and other maneuvers; complete bilateral study
- 93971 Duplex scan of extremity veins including responses to compression and other maneuvers; unilateral or limited study

## OFFICE ELECTROCARDIOGRAMS

Russell D. White • George D. Harris

The electrocardiogram (ECG) is a graphic description of the electrical activity of the heart, recorded from skin surface electrodes positioned to demonstrate this activity from a variety of spatial perspectives. The waves of electrical activity are represented as a sequence of deflections on the ECG (P wave, QRS complex, and T wave). The resting ECG is the most widely used cardiovascular diagnostic test in the United States. Current estimates are that half are performed or interpreted by clinicians without fellowship training in cardiology. The clinician supervising, performing, or interpreting ECGs must be familiar with the proper use of the machine and electrode placement. In addition, guidelines and clinical competency statements are available (see the Bibliography).

The validity of using the resting 12-lead ECG as a screening test for cardiovascular disease in asymptomatic individuals has never been demonstrated convincingly. One reason is the relatively low prevalence of ECG abnormalities in the general population (ranges from 1% to 10%) . Such a low prevalence limits the ECG's sensitivity for screening, its predictive accuracy, and its usefulness (Fig. 89-1). Likewise, the ECG can appear completely normal in patients experiencing an acute coronary event. Therefore, it is important for the clinician to consider each ECG in the context of the clinical situation. Pertinent to each ECG are the patient's age, risk factors, medications, symptoms, physical findings, and laboratory results as well as findings from any previous ECGs (for comparison).

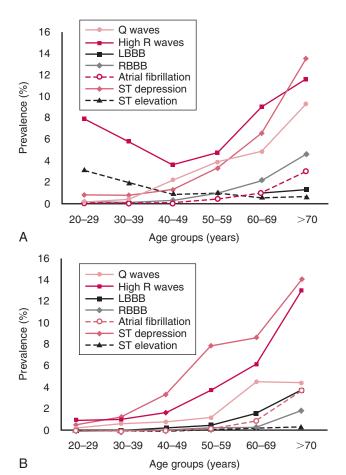

#### **INDICATIONS**

In the office, the following situations are the most common to warrant an ECG:

- Chest pain, especially if suspected to be of cardiac origin
- Palpitations
- Acute-onset dyspnea
- Syncope
- Presence of a new cardiac finding on examination (e.g., murmur, gallop, rub)
- Dysrhythmia recognition and management
- Baseline or longitudinal data for patients with hypertension, diabetes, chronic kidney disease (defined as glomerular filtration rate <60 mL/min), or other chronic diseases that might cause ECG changes or increase cardiac risk
- Preoperative screen for patients with known coronary artery disease (CAD) or who are at high risk for adverse cardiac events
- Electrolyte abnormalities that may cause ECG alterations (e.g., potassium, calcium)
- Before administration of pharmacologic agents that are known to have a high incidence of cardiovascular effects (e.g., medications causing a QT prolongation, cancer chemotherapy) and after starting therapy
- Before exercise testing (to note any contraindications)
- Individuals in special occupations that require high cardiovascular performance or who would immediately endanger others if they experienced a cardiovascular event

 Possibly for a baseline during a physical examination of those older than 40 years of age, especially patients with risk factors for CAD

Patients can be classified into three major groups when undergoing an ECG: (1) patients with known cardiovascular disease or dysfunction, (2) patients who are suspected of having or who are at increased risk of developing cardiovascular disease or dysfunction, and (3) patients with no apparent or suspected heart disease or dysfunction. For patients in the first two groups, an ECG is indicated if there has been a change in symptoms or if the therapy may change the ECG. The ECG may show changes during symptoms and in response to treatment, which would confirm a cardiac basis for symptoms. It also may demonstrate preexisting structural or ischemic heart disease (e.g., left ventricular hypertrophy, Q waves).

**Figure 89-1** Prevalence of ECG abnormalities in men (**A**) and women (**B**). LBBB, left bundle branch block; RBBB, right bundle branch block.

However, a normal ECG or one that remains unchanged from the baseline does not exclude the possibility that chest pain is ischemic in origin. The last group (group 3) represents a large proportion of the patients treated in the usual office practice.

**NOTE:** The routine use of a resting ECG to screen for CAD in asymptomatic adults is not recommended by the American College of Physicians or the Canadian Task Force on Preventive Health Care. The American Academy of Family Physicians and the U.S. Preventive Services Task Force recommend *against* routine screening for CAD with resting ECG in asymptomatic adults at low risk for events from CAD. They also find insufficient evidence to recommend for or against routine screening with resting ECG in patients at increased risk for events from CAD.

Although the American Heart Association likewise does not recommend routine or repeated ECGs for risk assessment, various ECG abnormalities have been reported to have predictive power. For example, the most common abnormal ECG findings (Q waves, ST segment depression, nonspecific T-wave abnormalities, left ventricular hypertrophy [LVH], and bundle branch blocks) on the resting ECG have been found to have independent predictive power for both coronary mortality and total cardiovascular mortality. In some studies, patients with one or more of these abnormalities were associated with two to four times increased cardiovascular risk (i.e., multivariate-adjusted relative risks between 2.0 and 4.0). These study results indicate that ECG abnormalities might suggest an increased clinical risk in certain patients and therefore warrant further investigation or risk reduction. Persistent abnormalities on the resting ECG on serial tracings are associated with a higher clinical risk than transient findings alone.

#### **CONTRAINDICATIONS**

- Emergent need for airway maintenance or management of breathing or circulation (these needs should be addressed before an ECG procedure is performed)
- Patient phobia, refusal, or inability to remain still or in one position (relative contraindication in life-threatening situation)
- Skin conditions (e.g., burns, infections) that would interfere with electrode placement (relative contraindication in lifethreatening situation)

#### **EQUIPMENT**

- Electrodes.
- ECG machine with appropriate patient cables and paper.
- If computerized storage is expected, a floppy disk (or other digital media) should be inserted or a connection made to the Internet, Intranet, or telephone line.

#### PREPROCEDURE PATIENT PREPARATION

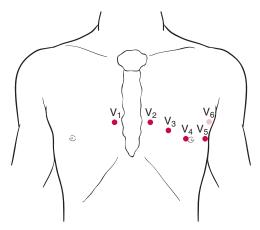

Explain the procedure to the patient and discuss why the patient needs to remain as immobile as possible, maintain normal respirations, and not talk during the procedure. Occasionally, there is a need to reassure the patient that the procedure is safe and will not cause an electrical shock (e.g., "It takes electricity out of you and does not put it in"). The patient should be aware that further cardiac work-up may be necessary regardless of the outcome of the ECG. The patient should also be aware that a normal ECG result does not eliminate the possibility of CAD or significant heart disease. Moreover, abnormal ECGs do not always indicate significant cardiac disease.

#### **TECHNIQUE**

Most modern ECG machines are so simple that an operator's manual is not needed. Standardization is accurate with digital machines, which often automatically adjust for excessive voltage. Perform the ECG procedure in a room away from powerful electrical equipment

(e.g., electric motors, x-ray equipment), if possible. Electrode placement remains the biggest challenge.

- 1. Place the patient in the supine position on the table. Generally, the patient has a pillow under his or her head. Arms should rest at the sides of the torso. Legs should be flat, apart, and not touching each other. If the patient is in a position other than supine (e.g., head elevated to relieve orthopnea), the heart's electrical axis is altered, possibly an issue when comparing serial tracings. In such cases, a note should be made on the ECG strip of degree or angle of patient elevation so that future ECGs can be obtained with the patient at the same angle for comparison. Although the patient's chest and distal extremities are exposed, keep the rest of the body covered. This protects patient dignity and should prevent shivering, which can cause a tremor artifact on the ECG tracing
- 2. Bring the ECG machine near the table and turn it on. The usual paper speed is 25 mm/sec and the amplitude 1 mV/10 mm.
  - NOTE: Older equipment, especially analog equipment, occasionally needs to be standardized. If available, review the operator's manual regarding standardization. Standardize the machine when it is tracing at 25 mm/sec by briefly depressing the standardization button. One millivolt should deflect exactly 10 mm, and full standardization should be used if possible. If standardization is not performed or is allowed to vary, evaluation of serial tracings is less accurate.
- 3. Wipe the areas for electrode placement with an alcohol swab. It may be necessary to shave some areas so that the electrodes stick. We recommend shaving after using the alcohol swab to avoid applying alcohol to any abrasions resulting from shaving. Gentle abrasion with a fine-grit sandpaper or equivalent may also reduce noise and artifact and improve the quality of the ECG. We also recommend using adhesive electrodes with a tab for fastening the clips from the cable lead.
- 4. Place the limb electrodes. The red electrode is for the left leg and is labeled "left leg." The electrode for the right leg is universally green and is labeled "right leg." The electrode for the right arm is often banded in white and labeled "RA." The electrode for the left arm is banded in black and labeled "LA." Traditionally, limb electrodes were placed on the wrists and ankles. However, with the development of high-quality disposable electrodes, many clinicians have started applying the limb electrodes below the hips and on the upper arms. Applying the electrodes more proximally may reduce motion artifact.
- 5. Place the chest electrodes in the following order (Fig. 89-2):
  - V<sub>1</sub> (red): fourth intercostal space at right sternal border
  - V<sub>2</sub> (yellow): fourth intercostal space at left sternal border

**Figure 89-2** Placement of electrodes. Note that  $V_6$  is in the same horizontal plane as  $V_4$  and  $V_5$ , but more lateral, in the mid-axillary line.

- $\bullet$  V<sub>4</sub> (blue): fifth intercostal space at the mid-clavicular line
- $V_3$  (green): halfway between  $V_2$  and  $V_4$
- V<sub>5</sub> (tan): anterior axillary line at the same level as V<sub>4</sub> (directly lateral and in the same transverse plane)
- $^{\bullet}$   $V_{6}$  (violet): mid-axillary line at the same level as  $V_{4}$  and  $V_{5}$  (again, directly lateral to  $V_{5})$

For a landmark in men, the nipples are usually in the mid-clavicular line and overlie the fourth intercostal space. For consistent placement, use only bony landmarks for precordial electrodes. The sternal angle, between the manubrium and body of the sternum, is immediately above the second intercostal space. The  $V_4$  through  $V_6$  electrodes are placed in the same horizontal plane (not necessarily in the same intercostal space).

6. Perform the ECG procedure with the electrodes in their proper locations. For dysrhythmias, an extended rhythm strip or another attempt at a 12-lead ECG may be indicated for improved technical quality. Multichannel machines are superior to single-channel machines for rhythm strips. When a second channel is available, it is best to display lead II for rhythm and  $V_5$  for ischemia. If three channels are available, it is best to display leads aVF,  $V_2$ , and  $V_5$ .

**NOTE:** For continuous monitoring (telemetry), any lead can be used; however, most coronary care units use a modified bipolar chest lead. The negative electrode is near the left shoulder and the positive is the traditional  $V_1$ . A third is placed at a more remote area of the chest and serves as a ground. However, of all leads,  $V_5$  is the most sensitive for the diagnosis of ischemia. Ventricular arrhythmias are more ominous when ischemia is present (see Chapter 87, Ambulatory Electrocardiography: Holter and Event Monitoring). If a single channel is all that is available and ischemia is a concern,  $V_5$  should be used.

 Remove the electrodes from the patient, dispose of them, and clean the areas on the patient where the electrodes were attached. Modern adhesive electrodes are dry and leave very little residue.

#### **INTERPRETATION**

Although computer interpretive programs provide the noncardiologist with a quick and convenient second opinion, they do not provide advice on what to do with an abnormality. The following discussion is aimed at supplementing the available interpretive programs with a suggested course of management, including trouble-shooting for errors.

#### **Limb Lead Reversal**

Limb lead reversal is the most common noticeable error involving the frontal leads. It usually occurs between the right and left arm electrodes, probably because these leads are usually grouped, bundled, or connected together. Lead reversal has become more common as inexperienced personnel replace ECG technicians. Fortunately, the right and left leg electrodes can be switched without affecting the recorded ECG. The clinician should consider arm lead reversal as a possibility whenever the computer interpretation is marked right axis deviation, especially if it is new compared with a previous tracing, or when precordial leads do not exhibit the normal R-wave progression. Also, the precordial leads and aVF will be normal, whereas limb lead I will be inverted. Normally, limb lead I somewhat matches V<sub>6</sub> in terms of morphology of the P-wave and QRS direction; this will not be the case with arm lead reversal. When every tracing from an ECG machine exhibits this pattern, the actual ECG leads may be mislabeled.

The second most common placement error is reversal of  $V_1$  and  $V_3$  (again, frequently in the same group or bundle of leads). This should be considered a possibility when R-wave amplitude does not increase from  $V_1$  to  $V_3$  and there is T-wave inversion in  $V_3$ .

Management includes repeating the ECG procedure after checking previous ECGs from the patient, checking the ECG machine, and verifying lead placement. If limb lead reversal is excluded and the finding is still not explained, check the precordial leads for normal R-wave progression. If the R waves do not progress normally, move the precordial leads to the patient's right side and record for the possibility of dextrocardia. If dextrocardia is confirmed, correlation with a chest radiograph is the next step.

#### Wolff-Parkinson-White

Wolff-Parkinson-White (WPW) is an ECG pattern characterized by a short PR interval followed by a delta wave and a prolonged QRS duration. The QRS duration may be longer than 120 milliseconds (msec), but it may also be shorter, depending on the degree of fusion of conduction. These characteristics are due to aberrant conduction of activation through an accessory pathway. WPW occurs in 1 of 10,000 individuals and can be entirely asymptomatic, or it can be associated with tachycardia and palpitations. When WPW is present, the ST segments cannot be used to identify ischemia. O waves are actually negative delta waves and are not due to infarction. Individuals who are incidentally found to have this ECG finding are usually otherwise normal. However, they should be guestioned about symptoms of palpitations or syncope. Also, a family history of syncope or sudden death could have significance. If either of these symptoms has occurred or the family history is positive, referral to an electrophysiology cardiologist is appropriate.

## Right Atrial Abnormality (Not Present on Prior ECGs)

If the right atrial abnormality or P-pulmonale is new compared with previous ECGs, consider the clinical possibilities of a pulmonary embolus (e.g., tachycardia, pleuritic chest pain, cough, fever, hypoxia, presence of cancer, or immobilization) versus an exacerbation of lung disease.

## Right Atrial Abnormality (Present on Prior ECGs)

If the right atrial abnormality is a consistent finding, examine the patient for chronic lung disease (e.g., prolonged expiration, hyperresonance, rhonchi and distant breath sounds, lowered diaphragms) and consider the overall history, including possible exposure to asbestos, coal dust, or cigarette smoke. Pulmonary function testing may be indicated.

## Left Atrial Abnormality (Not Present on Prior ECGs)

If the left atrial abnormality or P-mitrale is new compared with previous tracings, consider the clinical possibilities of new congestive heart failure (CHF) or mitral valvular insufficiency. Mitral valvular insufficiency is confirmed by a holosystolic murmur radiating into the axilla and, if necessary, by echocardiography.

## Left Atrial Abnormality (Present on Prior ECGs)

If the left atrial abnormality or P-mitrale is consistent compared with previous tracings, evaluate the ECG for additional LVH criteria. LVH plus left atrial abnormality can be an ominous marker for future events such as CHF, stroke, or death. Physical examination and an echocardiogram can confirm the findings.

## Right Axis Deviation (Not Present on Prior ECGs)

When right axis deviation is a new finding, it can be due to an exacerbation of lung disease, a pulmonary embolus, or simply a tachycardia. If right axis deviation is a change from previous ECGs, question the patient for symptoms consistent with an exacerbation of lung disease or a pulmonary embolus. If the patient has findings consistent with embolus, a nuclear ventilation/perfusion  $(\dot{V}/\dot{Q})$  scan or computed tomographic (CT) angiogram is usually indicated. If a  $\dot{V}/\dot{Q}$  mismatch or thrombus is noted, anticoagulation is appropriate.

#### Right Axis Deviation (Present on Prior ECGs)

Chronic right axis deviation is normal in those younger than 21 years of age and in athletes. It can also be a chronic finding in patients with lung disease, right ventricular hypertrophy, an old lateral wall myocardial infarction, or a left posterior hemiblock.

#### **Left Axis Deviation**

Left axis deviation (LAD) is the most common "abnormality" in adults, occurring in over 8% of patients. It can be part of the criteria for LVH, but in isolation it has little significance. Marked LAD (45% or more) is called *left anterior hemiblock* or *left anterior fascicular block*. If LAD is present and the patient is not known to be hypertensive, it may be worth efforts to exclude the diagnosis of hypertension with frequent blood pressure checks or ambulatory blood pressure monitoring (see Chapter 84, Ambulatory Blood Pressure Monitoring). LAD can also be seen after an old inferior wall myocardial infarction.

#### Right Bundle Branch Block

Right bundle branch block (RBBB) can be normal (occurring without underlying disease) or due to trauma, increased right ventricular pressure, ischemia, or infarction. An incomplete RBBB has a QRS duration of less than 120 msec and an RSR' pattern in V<sub>1</sub> and V<sub>2</sub> without an R wave greater than the amplitude of the S wave. It sometimes is simply called an RSR'pattern and usually is a normal finding. Very rarely, it can be associated with an atrial septal defect. Incomplete RBBB or right ventricular conduction delay (RVCD) is not necessarily a precursor of RBBB or any conduction abnormality. Such atypical right ventricular conduction patterns are seen more frequently in people younger than 21 years of age and in athletes, and they can also be normal variants. Although wide splitting of the second heart sound is a very common finding among normal patients, fixed splitting of the second heart sound can also be associated with an atrial septal defect. Remember that the abnormalities of the second heart sound must be heard in the sitting position because splitting is often wide in normal individuals when supine. If present, an echocardiographic air contrast ("bubble") study is indicated. Any pulmonary disease process can be associated with RVCD, and RVCD can occur acutely with exacerbation of lung disease or a pulmonary embolus. Clinical correlation is necessary; either treatment of the lung disease or a V/Q scan/CT angiogram might be indicated.

#### **Left Bundle Branch Block**

Left bundle branch block (LBBB) can result from severe trauma (car accident), ischemia, or infarction. It is often associated with LVH or left ventricular dilation. LBBB can also result from fibrosis of the conduction system. LBBB has a weak predictive power in a young, asymptomatic population (consistent with Bayes' rule), but is quite ominous in an older population as a marker for an increased risk of death, stroke, and CHF. Incomplete LBBB and the

hemiblocks are usually not associated with cardiac disease. Clinical correlates, including the cardiac examination, should direct any further studies in response to a new LBBB. If the patient has an enlarged heart with signs or symptoms of CHF, an echocardiogram is usually indicated. If a patient with LBBB has prolonged ischemic-type chest pain, the patient is experiencing an ST-elevation myo-cardial infarction until proven otherwise. Percutaneous coronary intervention, or thrombolysis if percutaneous coronary intervention is not available, is indicated. If the patient is asymptomatic and clearly not having an acute myocardial infarction, unfortunately neither the resting nor the exercise ECG can be used as a diagnostic tool. Instead, a stress echocardiogram or a nuclear perfusion test is required.

#### Right Ventricular Hypertrophy

Right ventricular hypertrophy can be a normal finding in people younger than 21 years of age and in athletes. It can be associated with chronic obstructive pulmonary disease, primary and secondary pulmonary hypertension, some types of congenital heart disease, pulmonary embolus, and CHF. Clinical correlation is indicated. If the right ventricular hypertrophy is new compared with previous tracings, consider the clinical presentation for pulmonary embolus or exacerbation of lung disease. The patient may require hospitalization and treatment with heparin for pulmonary embolism, or bronchodilators, antibiotics, and steroids for chronic obstructive pulmonary disease. If the pulmonary disease ECG criterion is not a new finding, examine the patient for chronic lung disease (e.g., prolonged expiration, hyperresonance, rhonchi and distant breath sounds, lowered diaphragms) and consider the overall medical history, including possible exposure to asbestos, coal dust, or cigarette smoke. Pulmonary function testing as well as an echocardiogram may be indicated.

#### Left Ventricular Hypertrophy

Left ventricular hypertrophy requires clinical correlation, beginning with blood pressure measurement and physical examination for cardiac size and murmurs and morbid obesity. A complete medical history should be obtained with emphasis on symptoms of aortic valve disease (e.g., angina, syncope) and CHF. If CHF or aortic stenosis is suspected after the history or examination or there is an abnormal cardiac examination, an echocardiogram may be indicated. LVH is one of the most ominous ECG indicators of risk for future cardiovascular events in patients older than 30 years of age.

#### **ST Segment Depression**

Acute ST segment depression can be associated with ischemia, unstable angina/non-ST segment elevation myocardial infarction (acute coronary syndrome), electrolyte abnormalities, osmolality changes, hyperventilation, standing up, and certain drugs. An ECG should be obtained in any patient with chest pain of uncertain etiology because an acute ST shift can confirm that it is due to ischemia. ST segment depression may also be associated with subendocardial damage, as opposed to Q waves, which are usually associated with transmural damage from infarction. Although chronic ST segment depression is nonspecific as a marker for cardiac disease, it is associated with a poor outcome. It can be due to electrolyte abnormalities and drugs, particularly digoxin. The patient should be questioned about a past or present history of cardiac ischemic pain. Blood chemistries, including electrolytes, glucose, calcium, magnesium, blood urea nitrogen (BUN), and creatinine, should be obtained. All medications should be recorded carefully and any nonprescription drugs that the patient may be taking should be noted. Many nonprescription drugs, especially from other countries, contain diuretics and even digoxin.

#### **Prolonged QT Interval**

Diagnosis of prolonged QT interval is complicated by the inherent difficulty in identifying T-wave end and the inaccuracy of Bazett's formula when correcting for heart rate. It may be preferable to judge the QT interval prolonged when it changes in length or when it exceeds 50% of the R-R interval. QT prolongation can be due to multiple causes, but its importance is its association with premature ventricular contractions, ventricular tachycardia, and ventricular fibrillation; in other words, it is associated with vulnerability to a lethal arrhythmia. The following is a list of some of the conditions that can cause QT prolongation: hereditary syndromes (rare), electrolyte-metabolic abnormalities (hypokalemia, hypomagnesemia, or hypocalcemia), medications (e.g., type Ia antiarrhythmics such as quinidine; tricyclic antidepressants, antihistamines, anticholinergic drugs, antibiotics [e.g., macrolides], and antifungals), central nervous system disorders, systemic illnesses, and myocardial infarction. Obtain blood chemistries, including electrolytes, glucose, calcium, magnesium, BUN, and creatinine. Take a careful medication history, including noncardiac drugs such as decongestants, anti-GERD (gastroesophageal reflux disease) medications, and antibiotics. Ask specifically about any family history of syncope or sudden death.

#### **Troubleshooting**

- Arm lead reversal can result in false-negative or false-positive signs of ischemia.
- Older ECG machines use thermal-head printers that automatically adjust for tracing intensity. Some newer machines use laser printers that actually write the grid. They use regular paper rather than the more expensive, heat-sensitive grid papers. Extra paper, styluses, or printer cartridges should always be available.
- For a wandering baseline, there is either poor electrode contact or a bad cable, or the patient is slowly moving or breathing deeply. For older equipment, especially analog equipment, the machine may not be warmed up adequately.
- A jagged baseline is from wall current (AC) interference, a broken wire, improper grounding, or other electrical interference.
- For older equipment with heat-sensitive paper, if the baseline is too light or thin, the stylus is not hot enough. If the baseline is too thick, the stylus is too hot (refer to the operating manual).
   Improper stylus pressure is detected by using the standardization pulse. With proper pressure, the standardization pulse should produce a tracing with sharp corners. Rounded or exaggerated angles indicate improper pressure.
- Technicians and other medical personnel responsible for obtaining ECGs should have training and periodic retraining in skin preparation, lead placement, and patient positioning.

#### **COMPLICATIONS**

- Local skin irritation or allergic reaction to electrode placement or adhesive
- Patient distress over abnormal ECG
- Incorrect interpretation because of improper lead placement, ECG performance, or computer or clinician error
- Unnecessary diagnostic work-up or treatment (and the adverse events associated with these additional interventions) because of false-positive results, no prior ECG tracing with which to compare, an inadequate clinical correlation, or a normal ECG variant

#### **POSTPROCEDURE PATIENT EDUCATION**

For persistent symptoms, the patient should schedule a follow-up visit with his or her clinician, regardless of the ECG result. The

patient should be given the results of the ECG, as well as instructions for medications, follow-up, or further work-up, as necessary. The clinician may wish to give the patient a copy of the ECG or ECG interpretation for his or her personal records.

#### **PATIENT EDUCATION GUIDES**

See patient education form available online at www.expertconsult.com.

#### **CPT/BILLING CODES**

93000 Electrocardiogram, routine, with at least 12 leads; with interpretation and report

93005 Tracing only, without interpretation and report

93010 Interpretation and report only

**NOTE:** An ECG is usually needed to rule out a contraindication to exercise testing; however, Medicare will not reimburse for an ECG on the same day as an exercise test. For this and other reasons, it is usually better to bring the patient back on another day for an exercise test. Before every exercise test, another comparison ECG is performed; it is just not reimbursable by Medicare.

# **ECHOCARDIOGRAPHY**

Grant C. Fowler • Terry Reynolds

The prevalence of heart disease will continue to increase in the United States as the population ages. The amount of heart disease managed by primary care clinicians will also continue to increase. In many cases, both the management and the prognosis of heart disease are based on the amount of remaining viable myocardium. This is especially true for patients with congestive heart failure (CHF), cardiomyopathy, arrhythmias, and ischemic heart disease. One method of quantifying the remaining viable myocardium is to assess the ejection fraction. In fact, the most common reason echocardiography is currently performed in the United States is to determine the ejection fraction.

Many common symptoms, signs, or diagnoses of heart disease (e.g., palpitations, cardiomegaly on electrocardiogram [ECG] or chest x-ray, atrial fibrillation, CHF) are evaluated or managed based on data from echocardiography (Table 90-1). In certain situations, the more readily available the echocardiogram, the better the management. For example, acute chest pain is managed differently when echocardiography is immediately available. Even extracardiac causes for acute chest pain, some of which can be life threatening (e.g., pulmonary embolus, aortic dissection), can be diagnosed with echocardiography. If an acute myocardial infarction (MI) is diagnosed, risk stratification can be performed immediately. Complications from an acute MI can also often be diagnosed early.

Other common diagnoses that can be made or evaluated in the primary care clinician's office with echocardiography include mitral valve prolapse, dilated left atrium (important for patients with atrial fibrillation), left ventricular hypertrophy, transient ischemic attack, and ischemic heart disease. Whether in the clinician's office, the hospital, or the emergency department, a rapid diagnosis of pericardial tamponade or a pericardial effusion may be life-saving. Furthermore, if pericardiocentesis is needed, the risk of complications is significantly reduced if it is performed under ultrasonic guidance (see Chapter 214, Pericardiocentesis).

Improvements in image quality, portability, and affordability for real-time sonography have allowed it to become a valuable adjunct for the clinician in the office, in the hospital, or in the emergency department. Albeit not by much, the cost of echocardiography equipment has also decreased as the technology has expanded and improved. Consequently, echocardiography has seen some of the most rapid growth among procedures performed by primary care clinicians (see Chapter 94, Stress Echocardiography). For those clinicians with a large number of adult patients, two-dimensional (2D) and M-mode echocardiography may be a welcome addition to their practice. If the primary care clinician is uncomfortable performing echocardiography, contractors are available to provide sonographers. Over-reading services are also available (see the "Suppliers" section). This chapter predominately describes the performance of a 2D/M-mode echocardiogram with a brief summary of common findings. Since color and Doppler flow imaging are helpful for almost all echocardiograms, especially for those assessing the hemodynamic severity of an abnormality, they will also be discussed briefly. For a discussion of ultrasound principles and concepts, and for information regarding limited echocardiography, see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography (Clinical Ultrasonography). Electromechanic dissociation, pericardial effusion, pericardial tamponade, and assessing intravascular volume status, right ventricular strain/dysfunction, and acute pulmonary hypertension (e.g., pulmonary embolism) are briefly discussed in that chapter. (Assessing for possible pulmonary hypertension is also discussed in the Interpretation section of this chapter.)

Two-dimensional echocardiography provides the clinician with cross-sectional, real-time images of various cardiac structures. Using 2D, cardiac chambers, walls, valves, and other structures can be observed as they move through the cardiac cycle. Freeze-framing and the use of calipers allow the clinician to measure certain structures, if needed, at various points during the cardiac cycle.

M-mode echocardiography produces graphic images in which time makes up the horizontal axis and the structures in motion being scanned compose the vertical axis. In other words, wherever the cursor is placed on the image, a linear beam of ultrasound is directed through the corresponding tissue and movement of the structures is graphically imaged over time. The resultant M-mode tracing can then be used to look at excursion and contraction patterns as well as to precisely measure distances from the various horizontal structures over time. Chamber dimensions, wall thicknesses, and valve excursions can be measured precisely throughout the cardiac cycle. From chamber dimensions, an ejection fraction can be estimated.

Doppler flow imaging is used to measure the velocity of blood flowing over certain structures. Using the Bernoulli equation, pressure gradients (e.g., across a valve) can also be determined. As with M-mode, time and the cardiac cycle are graphed along the horizontal axis while the vertical axis consists of blood velocity in meters per second. By convention, flow toward the transducer is depicted above the baseline and flow away from the transducer is depicted below the baseline. Pulsed wave (PW) technology and measurements utilize tiny, three-dimensional sample volumes to detect the exact location of any abnormalities. However, PW Doppler is limited when there is high-velocity flow. Continuous wave (CW) technology utilizes two crystals (one continuously emitting sound waves, the other continuously listening for echoes) and can measure high velocities (e.g., stenotic valves). However, it is of limited use for localizing abnormalities. As a result of these limitations, both PW and CW should be utilized with every valve. Color flow Doppler is a special adaptation of PW technology. It uses thousands of sampling volumes to produce a color image of velocities. By convention, flow away from the transducer is blue and flow toward the transducer is red. The intensity of the color increases with the velocity.

#### **INDICATIONS**

- Determine ejection fraction (most common indication)
- Acute chest pain
- Acute or old myocardial infarction
- Atrial fibrillation
- Cardioversion preparation

TABLE 90-1 Common Symptoms and Differential

Diagnosis for Echo	ocardiography
Reason for Echocardiography	Differential Diagnosis
Chest pain	Aortic dissection Coronary artery disease: acute myocardial infarction or angina Hypertrophic cardiomyopathy Pericarditis Pulmonary embolism Valvular stenosis
Heart failure	Dyspnea Hypotension Left ventricular diastolic dysfunction Left ventricular systolic dysfunction (global or segmental) Pericardial disease Right ventricular dysfunction Valvular heart disease
Palpitations	Congenital heart disease (e.g., atrial septal defect, Ebstein's anomaly) Left ventricular systolic dysfunction Mitral valve disease Pericarditis Structural cardiac disease
Murmur: systolic	Aortic stenosis, subaortic obstruction, hypertrophic obstructive cardiomyopathy Flow murmur (valve abnormality) Mitral regurgitation Pulmonic stenosis Tricuspid regurgitation Ventricular septal defect
Murmur: diastolic	Aortic regurgitation Mitral stenosis Pulmonic regurgitation Tricuspid stenosis
Cardiomegaly on chest x-ray	Dilated cardiomyopathy Pericardial effusion Specific chamber enlargement (e.g., left ventricle in chronic aortic regurgitation)
Systemic embolic event	Aortic valve disease Left atrial thrombus (only diagnostic if seen, otherwise transesophageal echo needed) Left ventricular systolic function and segmental wall motion abnormalities (aneurysms) Left ventricular thrombus Mitral valve disease Patent foramen ovale

Adapted from Otto CM: Textbook of Clinical Echocardiography, 2nd ed. Philadelphia, WB Saunders, 2000.

- Cardiomegaly on chest radiograph
- Congestive heart failure
- Dyspnea (possibly due to cardiac origin)
- Embolus (systemic or pulmonary)
- Hypotension (possibly due to cardiac origin)
- Hypertensive heart disease
- Ischemic heart disease
- Mitral valve prolapse
- Murmur
- Palpitations
- Pericardial effusion, electromechanical dissociation, or suspected pericardial tamponade
- Suspected cardiomyopathy
- Suspected infectious endocarditis
- Suspected left ventricular hypertrophy (e.g., LVH on ECG)

- Transient ischemic attack
- Valvular defect, stenosis, regurgitation, or insufficiency
- Ventricular arrhythmias (with suspected cardiac structural abnormality)

#### **CONTRAINDICATIONS**

- Patient too unstable or too uncooperative to be scanned
- Patient needs Doppler flow imaging or a color Doppler scan, and the equipment does not have this capability

#### PREPROCEDURE PATIENT PREPARATION

Indications for the study and possible findings should be explained to the patient. The patient should be prepared to change positions, if possible, while being scanned. The patient should be prepared for adequate gel and pressure from the transducer to be applied to the parasternal, apical, suprasternal, and, possibly, subxiphoid areas of the chest and abdominal walls. The patient should be gowned and in the supine or left lateral decubitus position.

# **EQUIPMENT**

- For best images, an ultrasound machine with several probes of different frequency should be available. Among these probes, a low-frequency (e.g., 2.5 MHz) probe with 2D, M-mode, and cardiac Doppler capabilities is necessary. An ultrasound machine with harmonic imaging ensures high-quality images. A method of recording and storing the data (e.g., server, DVD, VCR) is also needed for documentation. For limited scans in emergency situations, a machine without Doppler capability can be used.
- Ultrasonic jelly (and towels to clean up after scanning).
- Patient gown.

# **TECHNIQUE**

# Two-Dimensional Echocardiography

Viewing the front of the chest, if the 12 o'clock position is considered cephalad and the 6 o'clock direction caudal, the axis of the heart is usually located in a line drawn between the 10 o'clock and the 4 o'clock positions. Placing the marker dot of the transducer at about the 10 o'clock position usually produces the long-axis view of the heart, especially if the probe is located parasternally. A line drawn between the patient's right shoulder and left hip also approximates the long axis of the heart. The long-axis view is essentially the longitudinal view of the heart, if described in the conventional terminology of ultrasound for the remainder of the body. Rotating the marker dot almost 90 degrees or perpendicular to the long axis, to the 2 o'clock position, produces the short-axis view of the heart. This is essentially a transverse view of the heart (Fig. 90-1). A line drawn between the left shoulder and the right hip also approximates this axis

Because the patient is usually lying in the left lateral decubitus position while being scanned and the transducer is placed on the anterior chest wall (or abdominal wall for the subxiphoid view), the

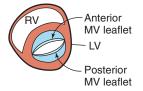

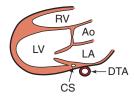

Figure 90-1 Parasternal short-axis view at the level of the mitral valve (MV). LV, left ventricle; RV, right ventricle. (From Reynolds T: The Echocardiographer's Pocket Reference, 2nd ed. Phoenix, School of Cardiac Ultrasound at Arizona Heart Institute, 2000.)

transducer edge will be noted at the top of the image. Posterior cardiac structures will be located at the bottom (inferior aspect) of the image. With the usual orientation, if the directional marker is noted on the right side of the image, objects to the right of the screen will correspond to objects near the marker dot on the transducer.

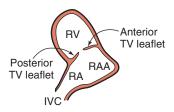

- 1. With the patient in the left lateral decubitus position, attempt to scan by first placing the transducer in the parasternal location (third to fourth intercostal space, next to the sternum) or the apical location (inferolateral to the left nipple at the point of palpated maximal cardiac impulse [PMI]). These same two traditional auscultatory points are used for a stethoscope. If the best window is found at the apical location, skip to step 12.
- 2. When scanning parasternally, the probe will be rotated so that the marker dot is either in the 10 o'clock (long-axis) or the 2 o'clock (short-axis) position. The short-axis view at the level of the mitral valve is often a good view for assessing the adequacy of the window, since the mitral valve is usually prominent and easily located (see Fig. 90-1).

**NOTE:** Some ultrasound equipment places the marker dot 180 degrees away from this standard orientation (that is, the 4 o'clock position) is what would typically be the 10 o'clock position). To determine the orientation of the probe, the directional marker on the image should be found. It corresponds with the marker dot on the probe and should be displayed on the right side of the display for cardiac imaging.

- 3. Small changes in patient position (e.g., rolling the patient further onto his or her left side) or working with the patient's breathing may improve the quality of the image. These adjustments cause the lingula of the lung to fall away from the heart, often providing a better window.
- 4. For unresponsive patients, those who cannot be moved, patients with chronic obstructive pulmonary disease, or other technical difficulties impairing the use of ultrasound in the parasternal position, the subxiphoid position will often provide a good window. Place the transducer directly below the xiphoid and angle it toward the patient's left shoulder with the marker dot toward the patient's left side. If this is the only location where an adequate window can be obtained, skip to step 16.
- 5. If a good window can be found at the parasternal short-axis view, rotate the transducer 90 degrees to the parasternal longaxis view (Fig. 90-2). With this view, observe the anterior and posterior leaflets of the mitral valve as it is scanned lengthwise. With prolapse, the leaflets will close beyond 90 degrees or cross the plane of the mitral annulus. True prolapse is often associated with thickened valves. Also with this view, the right ventricle is seen at the superior portion of the image, and the interventricular septum is noted as the inferior border of the right ventricle. Beneath the interventricular septum to the left of the image is the left ventricular chamber bordered by its posterior wall. Note that the ventricular walls thicken during systole, reducing the size of the ventricular cavity. Very little of the apex can be visualized with this view, because it is beyond the left side of the image. The left atrium is to the right side of the image, immediately inferior to the aortic root. The left atrial

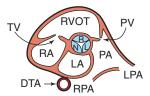

**Figure 90-2** Parasternal long-axis view. Ao, aortic root; CS, coronary sinus; DTA, descending thoracic aorta; LA, left atrium; LV, left ventricle; RV, right ventricle. (From Reynolds T: The Echocardiographer's Pocket Reference, 2nd ed. Phoenix, School of Cardiac Ultrasound at Arizona Heart Institute, 2000.)

**Figure 90-3** Parasternal long-axis view of the right ventricular inflow tract (RVIT view). IVC, inferior vena cava; RA, right atrium; RAA, right atrial appendage; RV, right ventricle, TV, tricuspid valve. (From Reynolds T: The Echocardiographer's Pocket Reference, 2nd ed. Phoenix, School of Cardiac Ultrasound at Arizona Heart Institute, 2000.)

diameter should be about the same as the aortic root diameter. If either is markedly larger than the other or more than 4 cm in their anteroposterior diameter, they are considered dilated. The descending thoracic aorta is noted behind the left atrium. Rotate the transducer slightly clockwise if a better longitudinal view of the aorta is desired.

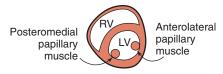

- 6. To obtain the long-axis view of the right ventricular inflow tract (RVIT) view, from the parasternal long-axis view, tilt the transducer inferomedially or toward the right hip. This is a good view in which to study the tricuspid valve, right atrium, and the right ventricle (Fig. 90-3). The posterior and anterior tricuspid leaflets separate the right atrium from the right ventricle. In fact, this is about the only view where the posterior leaflet of the tricuspid valve can be seen. Liver tissue is usually noted adjacent to the diaphragmatic wall of the right ventricle.
- 7. After angling the probe back again to the parasternal long-axis view, rotate the transducer 90 degrees so that the marker dot is at the 2 o'clock position. This will produce the parasternal short-axis view again (see Fig. 90-1). Note the appearance in real time of the opening and closing mitral valve. Some have likened this image to that of a "fish mouth" opening and closing, especially if there is any stenosis. Without stenosis, the lateral and medial commissures of the valve are easy to distinguish. At this level, the ventricular wall can be divided into six segments, and the contractility of all of the segments should be observed (see step 10). In the normal heart, the segments should be contracting uniformly and symmetrically. The tricuspid valve may be seen above and to the left of the mitral valve.
- 8. Next, without actually moving or rotating the transducer, merely angle it more cephalad toward the base of the heart to observe the aortic valve (Fig. 90-4). In this transverse view of the aortic valve, it produces a characteristic "Y sign" when the leaflets are closed. If the valve itself is viewed as the face of a clock, the commissures are noted in the 2, 6, and 10 o'clock positions at the edges of the Y. When the valve is open in systole, it should produce a triangular shape. If it produces an oval shape with opening, the aortic valve is bicuspid. This is one of the most common abnormal findings on adult echocardiography, occurring in 1% to 2% of the population. If it is

**Figure 90-4** Parasternal short-axis view at the level of the aortic valve. DTA, descending thoracic aorta; L, left coronary cusp; LA, left atrium; LPA, left pulmonary artery; N, noncoronary cusp; PA, pulmonary artery; PV, pulmonary valve; R, right coronary cusp; RA, right atrium; RPA, right pulmonary artery; RVOT, right ventricular outflow tract; TV, tricuspid valve. (From Reynolds T: The Echocardiographer's Pocket Reference, 2nd ed. Phoenix, School of Cardiac Ultrasound at Arizona Heart Institute, 2000.)

found the patient should also be scanned for coarctation of the aorta, because 50% to 80% of those with aortic coarctation will have a bicuspid aortic valve (see the suprasternal notch view, step 21). At this level of the parasternal short-axis view, the right ventricular outflow tract (RVOT) can be seen curving above and around the aortic valve. The tricuspid valve is noted to the left of the aortic valve and the pulmonary valve is located superiorly and to the right. The right ventricle is located between the two. The right atrium is located in the inferior portion of the image to the left of the aortic valve. The left atrial appendage can often be seen to the far right of the aortic valve, and the left atrium is noted inferior or posterior to the aortic valve. Part of the atrial septum can be noted between the atria. The three cusps of the aortic valve are labeled the right, left, and noncoronary cusps. The right cusp is located next to the right ventricular outflow tract, the noncoronary cusp closest to the right atrium, and the left coronary cusp next to the left atrium. In a normal heart, the corresponding right and left coronary arteries originate from the same-labeled cusps.

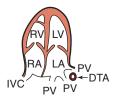

- 9. Tilting the transducer yet more superiorly, beyond the aortic valve, the aortic root can be visualized in its short axis (transversely). At this level, on the right side of the image of the aortic root, the pulmonary artery can often be noted to bifurcate into the right and left pulmonary arteries.
- 10. Next, angle the probe back through the mitral valve, down to the level of the papillary muscles (Fig. 90-5). This level provides an excellent view for assessing left ventricular wall motion and the severity of left ventricular hypertrophy if it is present. At this level, the left ventricular wall can again be divided into six segments—the anterior, anteroseptal, anterolateral, inferolateral (posterolateral), inferoseptal (posteroseptal), and inferior (posterior) segments—which are all visualized. This same segmentation system can be used on the parasternal short-axis view at the level of the mitral valve. Each of the segments should contract in a uniform manner. With coronary artery disease, determining which wall becomes hypokinetic with ischemia may predict which coronary artery is obstructed (see "Findings and Interpretation" section). Usually two papillary muscles are visualized at this level, one located anterolaterally and the other posteromedially. At this level, only part of the right ventricle can usually be visualized, and it will be to the left of the image.
- 11. Next, slide the transducer slightly toward the apex and obtain a short-axis view of the ventricles at the apex (Fig. 90-6). By convention, the left ventricular wall is divided into only four segments (anterior, lateral, septal, and inferior [posterior]) at this level. In the normal heart, all four segments will contract uniformly.
- 12. By moving the transducer to the apex, which can be located by palpating the PMI inferolateral to the left nipple, the apical four-chamber view can be obtained (Fig. 90-7). At this position, the majority of scanning is usually performed with the marker dot at the 3 o'clock position. Angle the transducer back up toward the base of the heart to obtain the best possible fourchamber image. To confirm the orientation while scanning, note that the septal leaflet of the tricuspid valve is closer to the apex than the anterior leaflet of the mitral valve. By convention, the tricuspid valve and the right ventricle should be on the left side of the image. The right ventricle can usually be distinguished from the left ventricle because the right ventricle has the echogenic moderator band extending from the apex to the septal wall. Again, the right ventricular wall is more trabeculated than the left ventricular wall. With this view, again observe the ventricular wall motion for uniformity of contraction. From this transducer position, observe the valves again for abnormalities.
- 13. Tilt the transducer slightly anteriorly, toward the anterior chest wall (tail of transducer is tilted downward slightly), from the apical four-chamber view to obtain the apical five-chamber view (Fig. 90-8). This view provides an excellent image of the

**Figure 90-5** Parasternal short-axis view of the left ventricle at the level of the papillary muscles. LV, left ventricle; RV, right ventricle. (From Reynolds T: The Echocardiographer's Pocket Reference, 3rd ed. Phoenix, School of Cardiac Ultrasound at Arizona Heart Institute, 2007.)

**Figure 90-6** Parasternal short-axis view at the level of the apex. LV, left ventricle; RV, right ventricle. (From Reynolds T: The Echocardiographer's Pocket Reference, 2nd ed. Phoenix, School of Cardiac Ultrasound at Arizona Heart Institute, 2000.)

**Figure 90-7** Apical four-chamber view. DTA, descending thoracic aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PV, pulmonary vein; RA, right atrium; RV, right ventricle. (From Reynolds T: The Echocardiographer's Pocket Reference, 2nd ed. Phoenix, School of Cardiac Ultrasound at Arizona Heart Institute, 2000.)

**Figure 90-8** Apical five-chamber view. Ao, aortic root; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (From Reynolds T: The Echocardiographer's Pocket Reference, 2nd ed. Phoenix, School of Cardiac Ultrasound at Arizona Heart Institute, 2000.)

**Figure 90-9** Apical two-chamber view. CS, coronary sinus; LA, left atrium; LAA, left atrial appendage; LV, left ventricle. (From Reynolds T: The Echocardiographer's Pocket Reference, 2nd ed. Phoenix, School of Cardiac Ultrasound at Arizona Heart Institute, 2000.)

left ventricular outflow tract as well as an excellent view to exclude hypertrophic obstructive cardiomyopathy.

14. Return to the apical four-chamber view and rotate the transducer 90 degrees counterclockwise and tip it slightly laterally to obtain the apical two-chamber view (Fig. 90-9). The left ventricle and atrium will be visualized, separated by the mitral valve. With this image, the full length of the inferior wall of the left ventricle can be visualized. Observe this wall, along with the anterior wall of the left ventricle, for uniform contractility.

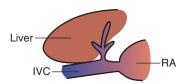

**Figure 90-10** Apical long-axis view. Ao, aortic root; LA, left atrium; LV, left ventricle; RV, right ventricle. (From Reynolds T: The Echocardiographer's Pocket Reference, 2nd ed. Phoenix, School of Cardiac Ultrasound at Arizona Heart Institute, 2000.)

- 15. Rotate the transducer counterclockwise so that the sector plane passes through the long axis of the heart to obtain the apical long-axis view (Fig. 90-10). The aortic root can be evaluated, while the aortic valve is noted to be contiguous with the base of the anterior mitral leaflet. This view is very similar to the parasternal long-axis view, but the apex is visualized from this position. With this image, the anterior interventricular septum and the inferolateral ventricular wall can be inspected for uniform contractility.
- 16. Moving the transducer to below the xiphoid, the subxiphoid (subcostal) four-chamber view (Fig. 90-11) can be obtained with the marker dot to the patient's left side. Usually a portion of the liver is used as a window. The ventricles will be to the right side of the image and the atria to the left side. The left ventricle and atrium will be located behind (below) the right ventricle and atrium. Inspect both the mitral valve and the tricuspid valve, and observe wall motion for uniformity of contraction.
- 17. From the subxiphoid four-chamber view, by tilting the transducer anteriorly, visualize the aortic valve lengthwise. This will again provide an image similar to that seen with the parasternal long-axis view. This technique of imaging may be very valuable if the standard parasternal long-axis image cannot be obtained because of technical difficulties.
- 18. From the subxiphoid four-chamber view, it is also possible to angle the transducer to visualize the entire atrial septum. This position is the most reliable for evaluating patients for atrial septal defects and patent foramen ovale.
- 19. From the subxiphoid view, the inferior vena cava (IVC) can be imaged (Fig. 90-12) and its diameters measured. The diameter of the IVC can be used to estimate right atrial pressure (RAP). With the marker dot toward the patient's feet and the transducer located in the midline, the long-axis view of the IVC can be obtained by angling slightly to the patient's right side. Normally the IVC is less than 2 cm in diameter and collapses more than 50% with inspiration. It will also normally collapse with pressure from the transducer. If it does not collapse, the formula in the "Findings and Interpretation" section can be used to estimate RAP. The IVC is thin-walled compared with the aorta, and it may appear to pulsate as a result of pulsations transmitted through solid tissue from the aorta. When it collapses with inspiration, these pulsations will be minimized.
- 20. In addition to what has been described, almost all of the parasternal short-axis views can be obtained scanning from the subxiphoid position. However, because of the depth of tissue necessary to scan from this position, there is usually some loss of resolution. This is especially true when compared with scanning from the parasternal position.

**Figure 90-11** Subxiphoid four-chamber view. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (From Reynolds T: The Echocardiographer's Pocket Reference, 2nd ed. Phoenix, School of Cardiac Ultrasound at Arizona Heart Institute, 2000.)

**Figure 90-12** Subxiphoid long axis view of inferior vena cava. IVC, inferior vena cava; RA, right atrium. (From Reynolds T: The Echocardiographer's Pocket Reference, 2nd ed. Phoenix, School of Cardiac Ultrasound at Arizona Heart Institute, 2000.)

- 21. Placing the transducer in the suprasternal notch with the marker dot to the patient's left side, scan the aortic arch in its long axis (Fig. 90-13) to provide what some call the "candy cane" view. With this image, the ascending aorta, its horizontal arch, and the proximal descending thoracic aorta can often be visualized. The origins of the left subclavian and left carotid arteries off of the aorta can usually be visualized, and occasionally the origin of the brachiocephalic artery can be seen. The right pulmonary artery is usually noted in short-axis view beneath the arch. This is the best view for excluding coarctation of the aorta.
- From the suprasternal view, by angling the transducer anteriorly and to the patient's right, the aortic root can often be visualized.
- 23. Further clockwise rotation can be used to obtain short-axis views from the suprasternal notch (Fig. 90-14). The right pulmonary artery can often be visualized in this manner. The right pulmonary artery is located between the aorta and the left atrium. It may be possible to visualize where the pulmonary veins drain into the left atrium.

**NOTE:** With the incidence of abdominal aortic aneurysm (AAA) increasing (5% to 7% of individuals over the age of 60), there is a strong correlation between individuals having an AAA and having an echocardiogram for other indications. With the patient already gowned and covered with jelly, it may be an excellent opportunity to screen for an AAA, even if no one is charged for the service.

# M-Mode Echocardiography

From the parasternal position, with either the long-axis or the short-axis view, M-mode images are usually obtained at three different levels: the level of the aortic valve, the level of the mitral valve, and the level of the papillary muscles in the left ventricle (Fig. 90-15). The subxiphoid transducer position can also be used for M-mode scanning when there is difficulty obtaining the standard parasternal images.

 At the mitral valve level, the anterior mitral leaflet makes an M-shaped pattern. The posterior leaflet moves as its mirror image to make a W-shaped pattern. The point of maximal early opening excursion is labeled E (Fig. 90-16). Next, the rapid filling phase

of early diastole occurs, and then the valve closes partially. While it is closing partially, the valve moves along the E to F slope. Note that this slope will be flatter if there is any condition impairing left ventricular filling. The E to F slope is followed by the remainder of diastole. During this phase, the A point indicates atrial systole. After atrial systole, the valve moves to the fully closed position labeled C. The closed leaflets then move together in ventricular systole until they separate at the D point. The B point is labeled but does not exist for normal patients. It only occurs if the A to C line is interrupted due to elevated left end-diastolic pressure or diastolic dysfunction (see Fig. 90-16).

To determine the E to F slope, first draw diagonal Line 4 through Line 1 (i.e., basically a continuation of Line 1). Draw a horizontal line (Line 5) near the bottom of the tracing where Line 4 intersects one of the time lines on the tracing. Draw Line 5 horizontal to the left for a distance corresponding to exactly 1 second on the tracing. Next, draw a vertical line (Line 6) from Line 5 to where it intersects Line 4. Line 6 should be perpendicular to Line 5. The length of Line 6 in millimeters is the E to F slope of the anterior leaflet in mm/sec (normal range 70 to 150 mm/sec). The E-point septal separation (EPSS) is the vertical distance between the E-point and the septal wall. It is enlarged for dilated cardiomyopathy and suggests a reduced ejection fraction.

2. With M-mode imaging at the aortic valve level (Fig. 90-17), typically only two aortic cusps are identified. At the onset of systole, they separate abruptly; at the end of systole they close abruptly, producing a "square box" on the image. Because normal aortic valves are very thin and often difficult to follow throughout the M-mode tracing, if the cusps are easily visualized, they may in fact be thickened. Following closure of the valve, the cusps normally remain opposed (closed) throughout diastole.

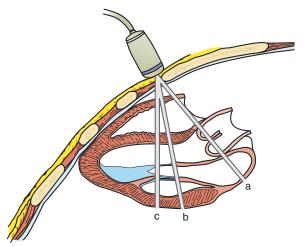

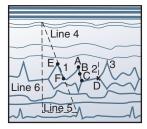

Figure 90-15 Levels to obtain M-mode images: Level of aortic valve (a); level of mitral valve (b); level of papillary muscle (c). (From Reynolds T: The Echocardiographer's Pocket Reference, 2nd ed. Phoenix, School of Cardiac Ultrasound at Arizona Heart Institute, 2000.)

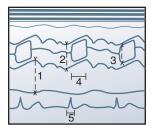

**Figure 90-16** M-mode at the level of the mitral valve. E, E-point (point of anterior leaflet maximal early opening); line I, MV E-F (mitral valve, E to F slope); line 2, MV EXC, vertical distance, mitral valve excursion (normal range 18 to 28 mm); line 3, EPSS (E-point septal separation [normal range 2 to 7 mm]); A, atrial systole; B, see text for explanation; C, valve fully closed; D, leaflets separate (valve opens). See text for explanation of lines 4, 5, and 6 and how to calculate E to F slope. (From Reynolds T: The Echocardiographer's Pocket Reference, 2nd ed. Phoenix, School of Cardiac Ultrasound at Arizona Heart Institute, 2000.)

The image at the level of the aortic valve is the most difficult to obtain with M-mode. Measurements of the left atrium, the aorta, and the valve cusp separation (opening diameter) are also taken at this level.

- 3. To obtain measurements of systolic time intervals, calipers can be used. The ejection time (LVET) is the time from the opening of the aortic valve until it closes. The pre-ejection period (PEP) is the time from the onset of the QRS to the onset of aortic valve opening (see Fig. 90-17).
- 4. Left ventricular measurements (e.g., systolic and diastolic dimensions) are best made slightly above the level of the papillary muscles, at the level of the chordae tendineae (Fig. 90-18). This is also an excellent view and level for obtaining right ventricular internal dimensions. Precise measurements of the thickness of all walls can also be made, in both diastole and systole.
- 5. For tricuspid valves, usually only one leaflet is traced with the M-mode for normal individuals. The RVIT view is an excellent view for tracing this single tricuspid leaflet. The pattern of motion for a single leaflet is similar to that of a mitral leaflet.
- 6. For pulmonary valve M-mode tracings, the parasternal short-axis view at the level of the aortic valve can be used. Once again, usually only one leaflet is traced for normal individuals. Because normal tricuspid cusps are very thin, it is often difficult to follow the leaflet motion throughout the cycle.

## Color and Doppler Flow Echocardiography

Multiple views can be used for this application, but inevitably the apical four-chamber view provides the best view for evaluating three of the valves. The parasternal short-axis view is often utilized to complete the evaluation of the valves. As each valve is being studied, the transducer should be placed so that it is as close as

**Figure 90-17** M-mode at the level of the aortic valve. I, LA (left atrium end-systolic dimension; normal range 1.9 to 4 cm); 2, AoR (aortic root end-diastolic diameter; normal range 2 to 3.7 cm); 3, ACS (aortic cusps separation in systole; normal range 1.5 to 2.6 cm); 4, LVET (left ventricular ejection time); 5, PEP (pre-ejection period). (From Reynolds T: The Echocardiographer's Pocket Reference, 2nd ed. Phoenix, School of Cardiac Ultrasound at Arizona Heart Institute, 2000.)

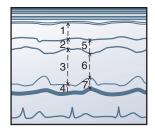

Figure 90-18 M-mode at the level of the mitral valve chordae tendineae. I, RVIDd (right ventricular internal diameter in diastole); 2, IVSd (interventricular septal thickness in diastole); 3, LVIDd (left ventricular internal diameter, diastole); 4, LVPWd (left ventricular posterior wall thickness in diastole); 5, IVSs (interventricular septal thickness in systole); 6, LVIDs (left ventricular internal diameter, systole); 7, LVPWs (left ventricular posterior wall thickness in systole). possible to being in line with the maximal flow across the valve. Transducer positioning can be guided by the resultant 2D image, by obtaining the maximal velocity on graphic image, by maximizing the sound, or by all three. Each operator develops his or her own technique for performing a complete examination and he or she should follow this technique with every evaluation (Fig. 90-19). A sample technique is provided here.

- 1. From the apical position, evaluate the left ventricular inflow tract with PW. Next, evaluate the left ventricular outflow tract.
- 2. The right ventricular or tricuspid inflow tract should then be evaluated. Next, either continuing to use the apical four-chamber view or shifting to the parasternal short-axis view at the level above the aortic valve, the right ventricular/pulmonary outflow tract should be evaluated.
- 3. Repeat the evaluation with CW.
- 4. If available, repeat the evaluation with color Doppler.

# **FINDINGS AND INTERPRETATION**

# Two-Dimensional and M-Mode Echocardiography Overview of Study

The quality of every study should be described in the report (e.g., good, fair, poor). This determination often depends on the quality of the window, the equipment used, and the body habitus of the

**Figure 90-19** Normal Doppler tracings. **A,** Left ventricular inflow tract (mitral valve). **B,** Right ventricular inflow tract (tricuspid valve). patient. Every report should also have at least a *qualitative* comment about the ejection fraction and segmental wall motion (e.g., normal, mildly impaired, moderately impaired, severely impaired). These parameters can also be measured *quantitatively*.

**EJECTION FRACTION.** With 2D, the ejection fraction can be calculated by summing a series of discs, if the equipment software is capable of tracing the ventricular cavity. It can also be calculated using M-mode measurements applied to Table 90-2.

# Ejection fraction = $[(EDV - ESV)/EDV] \times 100$

End-diastolic volume (EDV) and end-systolic volume (ESV) are both obtained from Table 90-2 using the left ventricular internal diameter in diastole (LVIDd) and then the left ventricular internal diameter in systole (LVIDs) as the dimension in the table. LVIDs is measured at the lowest vertical point of the septum. (See Table 90-3 for normal ranges.)

**NOTE:** At the Arizona Heart Institute, M-mode echocardiography is no longer used for determining the ejection fraction. Instead, at the end of every 2D study, the ejection fraction is either quantitatively measured using calipers or cavity tracings or estimated as normal (60%), moderately impaired (40%), or severely impaired (20%). As it turns out, various studies have compared qualitative

estimates of ejection fraction with calculated ejection fractions, especially for those patients with suboptimal imaging. Qualitative estimates have been found to be fairly accurate.

**SEGMENTAL WALL MOTION.** The American Society of Echocardiography has established the convention of dividing the heart into 17 segments (Fig. 90-20). These segments are distributed across three

levels. Anything above the level of the head of the papillary muscle, where it joins the mitral leaflet, is defined as the basal level of the heart. The mid-level of the heart is defined by the entire length of the papillary muscle. Anything below the level of the base of the papillary muscle, where it attaches to the ventricular wall, is designated the apical level.

allVS % thickening =  $[(IVSs - IVSd)/IVSd] \times I00$

(From Reynolds T: The Echocardiographer's Pocket Reference, 2nd ed. Phoenix, School of Cardiac Ultrasound at Arizona Heart Institute, 2000.)

Each wall segment has a corresponding coronary artery that perfuses it. In general, the anterior and anteroseptal walls and the entire apex are supplied by the left anterior descending coronary artery (LAD). Therefore, even though the apex is divided into four segments—anterior, lateral, septal, and inferior (posterior) segments—all of these segments are usually perfused by the LAD. Both the mid-level of the heart and the basal level are divided into six segments. The inferior (posterior) wall and the inferoseptal (posteroseptal) walls at the basal and mid-levels are supplied by septal perforators (posterior descending artery [PDA]) from the dominant coronary artery on the inferior (posterior) surface of the heart. The lateral walls of the ventricle (anterolateral and inferolateral [posterolateral]) above the apex are supplied by the left circumflex artery.

Wall motion in each segment is scored based on the recommendations of the American Society of Echocardiography:

Normally contracting segment (or hyperkinetic segment) = 1 Hypokinesia = 2 Akinesis = 3

Dyskinesis = 4

Aneurysmal segment (i.e., deformed during diastole) = 5

The wall motion score index is derived from the sum of all scores divided by the number of segments visualized. A normally contracting left ventricle has a wall motion score index (WMSI) of 1 (i.e., each of the 17 segments receives a wall motion score of 1; thus, the total score is 17 and the WMSI is 17/17 = 1). Patients at increased risk for future cardiac events after an acute MI can be identified in part by a high WMSI ( $\geq 1.7$ ).

Multiple views should be obtained with 2D echocardiography to compare the wall motion between various segments and to obtain the wall motion scores. Hypokinesis is defined as a less than 30% increase in wall thickening during systole and akinesis is defined as a less than 10% increase in thickening. Dyskinesis is present when the wall moves paradoxically outward when systolic thickening should be occurring. Comments should be made about wall motion, but more important, the walls should be scanned carefully for systolic thickening, which can be blunted by ischemia or infarction. Although wall motion scores may slightly overdiagnose the severity of an acute MI (e.g., severe ischemia can mimic an infarction), echocardiography is still much more accurate than an ECG. Of note, M-mode echocardiography has limited value when scanning for ischemia.

## **Acute Myocardial Infarction**

In the setting of acute MI, 2D is very helpful because it provides immediate information, is noninvasive, and can be performed at the bedside. It can usually determine not only the location of the infarct, but also the extent of the infarct. Because 2D is noninvasive, serial scans can be performed to track progression. An abnormal wall motion score or evidence of a complication on 2D is valuable prognostic data. These patients should be triaged for aggressive therapy, as opposed to those patients who can be safely discharged early. In comparison, when using an ECG to determine risk (either high or low), the severity or the location of the lesion cannot be predicted by ECG changes. Although an ECG may be helpful for diagnosing the acuity of an infarct, 2D is usually much more helpful overall because it can be used to actually stratify the patient's risk.

Mechanical complications of an acute MI that can be diagnosed early with 2D include pericarditis, pericardial effusion, pericardial tamponade, electromechanical dissociation, ventricular aneurysm, acute ischemic cardiomyopathy, mural thrombus, rupture of a papillary muscle (posteromedial much more commonly than anterolateral), and rupture of the ventricular free wall or septum.

#### **Atrial Fibrillation**

A left atrial dimension of greater than 4.5 cm indicates an increased risk of developing atrial fibrillation as well as a high probability of unsuccessful cardioversion. For more than 20 years, left atrial dilation in conjunction with mitral stenosis and atrial fibrillation has been associated with an increased risk of peripheral embolism and stroke. Such a finding should be managed aggressively with anticoagulation (if not contraindicated).

**NOTE:** Atrial appendage thrombi are best excluded by transesophageal echo.

# **Cardiac Tumors**

Cardiac tumors are seen as echogenic masses, and the majority (75% to 80%) of primary cardiac tumors are benign and curable. Thirty percent of benign tumors are myxomas, and they are usually attached by a stalk to the interatrial septum. They often partially or completely prolapse into the left ventricle during diastole.

#### Cardiac Tamponade and Pericardial Effusion

Cardiac tamponade and pericardial effusion (as well as electromechanical dissociation [EMD]) are discussed in Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography (Clinical Ultrasonography).

#### Cardiomyopathy

**DILATED CARDIOMYOPATHY.** Cardiomyopathy is defined as a primary disease of the myocardium and, by definition, is not due to ischemia or valvular disease. Dilated cardiomyopathy is by far the most common type of cardiomyopathy. It is characterized by dilation of all four chambers and reduced systolic function in both ventricles. Left ventricular dimensions (end-diastolic and end-systolic) and volumes are increased, whereas wall thicknesses are usually normal or slightly decreased. There will be a spherical configuration to the left ventricle with decreased left ventricular posterior wall and interventricular septal wall systolic thickening. As a result, there will be a decreased left ventricular ejection fraction. On M-mode, the left ventricular ejection time will be shortened with a resultant prolonged PEP/LVET ratio (>0.40). The distance of the anterior mitral leaflet from the septal wall (EPSS) is increased. The presence of a B-bump on the mitral valve tracing indicates increased left ventricular end-diastolic pressure (>15 mm Hg). There may be pulmonary hypertension, and for an ejection fraction less than 35%, an echogenic mural thrombus (in either ventricle) must be excluded. Mitral regurgitation is present to some degree in most patients with dilated cardiomyopathy.

HYPERTROPHIC CARDIOMYOPATHY. This form is much less common than dilated cardiomyopathy, and is an autosomal dominantly inherited disease with variable penetrance. The hypertrophy is usually asymmetrical and the interventricular septum is often involved (asymmetrical septal hypertrophy [ASH]). Less commonly, the left ventricular free wall or the apex can be asymmetrically involved. ASH can also be associated with obstruction of the left ventricular outflow tract, frequently as a result of the proximity of the anterior mitral leaflet to the septal wall (hypertrophic obstructive cardiomyopathy [HOCM]). Anterior motion of this leaflet during systole (systolic anterior motion [SAM]) can be noted on real-time or M-mode echocardiography to obstruct the outflow tract. Ventricular chambers are usually small. Most patients have mitral regurgitation as a result of SAM. On M-mode, midsystolic closure of the aortic valve can also be noted.

**RESTRICTIVE** (NONDILATED/NONHYPERTROPHIC) CARDIOMYOPATHY. This type is rare and is characterized by normal ventricular wall thicknesses and cavity size at initial presentation. The systolic function is normal and the heart failure is due to a stiff, hypertrophied ventricle with resultant impaired diastolic function. Biatrial enlargement is usually noted. The etiology is usually a fibrotic or infiltrative process such as hemochromatosis, sarcoidosis, or hypereosinophilic syndrome. As the disease progresses, the patient can develop a dilated cardiomyopathy. Although amyloid heart has a separate definition than fibrotic or restrictive, it can appear very similar on echocardiography. It is common to find an associated pericardial effusion with amyloid heart.

## Ischemic Heart Disease

Ischemic heart disease is assessed by looking at (1) global ventricular function (quantified with an ejection fraction) and (2) segmental wall function. Both should be assessed because both ischemia and infarction can cause significant segmental wall dysfunction without markedly impacting the ejection fraction.

## Left Ventricular Hypertrophy

A common cause of LVH is hypertensive heart disease, initially with concentric hypertrophy, increased left ventricular mass, impaired diastolic function, and normal systolic function. As LVH progresses toward end-stage heart disease, systolic dysfunction develops and the left ventricle dilates. The left atrium will eventually dilate because of decreased left ventricular compliance and possibly mitral regurgitation. (A left atrial dimension greater than 4.5 cm indicates an increased risk of developing atrial fibrillation.) Frequently, the aortic root will dilate and there will be associated aortic valve sclerosis. There may also be mitral annular calcification.

#### Concentric Hypertrophy

With concentric hypertrophy there is an equally distributed (uniform or globular) increase in ventricular wall thicknesses with normal ventricular dimensions (e.g., patients with valvular aortic stenosis or systemic hypertension). Left ventricular mass can be calculated to follow progression of LVH (see Table 90-3).

#### **Eccentric Hypertrophy**

Eccentric hypertrophy is commonly seen with aortic or mitral regurgitation. There is a spherical configuration to the left ventricle with normal wall thicknesses.

#### Mitral Valve Prolapse

In past years, MVP was overdiagnosed with echocardiography. As a result, a more formal definition was developed. Because the mitral valve, when closed, bulges normally or is "saddle-shaped" in the plane of the mitral annulus, true prolapse should be diagnosed only if a portion of the anterior leaflet prolapses beyond this plane. By new criteria, it must prolapse more than 2 mm beyond the mitral annular plane on the parasternal long-axis view or more than 1 cm on the apical four-chamber view. Posterior leaflet prolapse is diagnosed if any of the leaflet prolapses beyond the mitral annular plane in the parasternal long-axis view, the apical four-chamber view, or by more than 2 mm on the apical two-chamber view. The mitral annular plane is defined by drawing an imaginary line from the base of the anterior leaflet to the base of the posterior leaflet.

Myxomatous degeneration is the result of an increase in the middle layer of the valve, the spongiosa. With proliferation, the spongiosa replaces part of the fibrosa layer and the valve is weakened. Eventually, the valve becomes thickened, redundant, and elongated. In fact, it can develop the physical appearance of a hemorrhoid in its short-axis view. Myxomatous degeneration is usually diagnosed with 2D echocardiography; however, the thickness of the valve can be measured with either 2D or M-mode. The leaflets are considered redundant if they are 5 mm or more thick on the parasternal long-axis view during diastole, or more than 1.4 times the wall thickness of the posterior wall of the aorta during diastole. On M-mode, the thickness is considered abnormal if 5 mm or greater.

# Preliminary 2D and M-Mode Scanning before Using Color and Doppler Flow

Diastolic function is best determined with color and Doppler flow imaging. As mentioned previously, color and Doppler flow imaging also assist with determining the hemodynamic severity of lesions and are therefore helpful for assessing valvular abnormalities. Color-flow Doppler also produces jets that are characteristic for certain abnormalities. Eccentric jets are very helpful for aligning CW Doppler when attempting to optimize the spectrum. Such spectrum analysis is helpful for further quantifying regurgitant lesions.

**NOTE:** When assessing tricuspid valve regurgitation (TR) with color and Doppler flow imaging, note that TR is very common (90% of population). As a result, the regurgitation itself does not always need to be assessed. More importantly, the severity of the tricuspid regurgitation can be used to determine right-sided ventricular pressures. Pulmonary valve regurgitation is less common than TR, and mitral regurgitation is much less common. Aortic valve regurgitation is somewhat rare and its presence is always considered pathologic.

Despite the fact that the following disorders are best scanned with color and Doppler flow imaging, some information is usually obtained during preliminary 2D/M-mode scanning before using Doppler. This preliminary scanning is usually being performed while 2D/M-mode measurements are being taken (see Table 90-4 for normal values).

#### **Aortic Stenosis**

Aortic stenosis (AS) is usually the result of a degenerative process, rheumatic heart disease, or a bicuspid valve. With *degenerative rheumatic aortic stenosis*, the aortic cusps are usually thickened and there is associated concentric left ventricular hypertrophy, a dilated aortic root, a dilated left atrium, mitral annular calcification (50%), and a decreased mitral valve E–F slope.

As discussed earlier, the most common abnormality in adult echocardiography is a bicuspid aortic valve. With AS resulting from a bicuspid valve, thickened leaflets are often noted as well as the characteristic oval shape to the valve opening. All of the findings of rheumatic/degenerative AS are also seen, except for the mitral annular calcification.

#### **Aortic Regurgitation**

With aortic regurgitation, all of the findings of bicuspid aortic stenosis can be seen, except that the aortic root may not be dilated. Additional findings include premature closure of the mitral valve and premature opening of the aortic valve. Ventricular hypertrophy may be noted, either the eccentric or the globular type. There may also be an anatomic reason for the regurgitation (e.g., ascending aortic aneurysm, bicuspid aortic valve, valvular vegetation).

#### Mitral Stenosis

Mitral stenosis causes a decreased E-F slope and a decreased A wave on the M-mode tracing. The mitral leaflets may be thickened or they may be noted to have decreased mobility. In addition, the mitral valve opening orifice may be decreased, giving it the appearance of a "fish mouth" on 2D. The clinician should attempt to determine the degree of commissural and subvalvular involvement with the stenosis and scan for calcification of either the valve or the annulus. Possible associated findings include atrial dilation, a steep A-C slope, pulmonary hypertension, and an atrial septal defect. If the atrium is dilated, the clinician should scan for the presence of an echogenic thrombus. There may be right ventricular hypertrophy or dilation and evidence of right-sided volume overload. Clinicians should also scan for involvement of other valves. Doppler is needed to determine the orifice opening diameter when the leaflets are densely calcified, when there is an inadequate parasternal short-axis image, when there has been a surgical commissurotomy, or when there is extensive subvalvular involvement (e.g., a secondary orifice located below the valve).

# Mitral Regurgitation

With mitral regurgitation, there is usually echocardiographic evidence of left atrial and left ventricular volume overload patterns, as well as an associated right-sided overload pattern. Pulmonary hypertension may be noted. LVH may be present, and serial scans may be needed to monitor the progression of LVH. In addition, the mitral annulus may be dilated (normal  $2.3\pm0.5$  cm) on the apical four-chamber view. There may be an anatomic basis for the regurgitation: myxomatous degeneration of the valve with subsequent prolapse is the leading cause for regurgitation in the United States, but flail leaflets, annular calcification, or LV dysfunction (e.g., from ischemia) can be noted. The clinician should scan carefully to exclude flail leaflets.

# **Pulmonary Hypertension**

With pulmonary hypertension, RAP will be elevated. The dimensions of the IVC can be used to estimate RAP (Table 90-5).

With pulmonary hypertension, there will also usually be evidence of right ventricular hypertrophy (>5 mm thickness), especially if it is chronic. This hypertrophy may cause impingement on the left ventricle, resulting in a D-shaped left ventricle. The right atria and pulmonary artery may also be dilated. The interatrial septum may be deviated toward the left atrium.

TABLE 90-5 Estimating Right Atrial Pressure	
	RAP (mm Hg)
With pulmonary hypertension, RAP will be elevated. The dimensions of the IVC can be used to estimate RAP. IVC <2 cm diameter and collapses >50% with inspiration IVC <2 cm diameter and collapses <50% with inspiration IVC >2 cm diameter and collapses <50% with inspiration IVC >2 cm diameter and does not collapse with inspiration IVC >2 cm diameter and does not collapse with inspiration	5 10 15 20

IVC, inferior vena cava; RAP, right atrial pressure.

On M-mode, mitral valve disease may be diagnosed. Paradoxic septal motion as well as an increased septal wall thickness may be noted. There will also be abnormalities of the pulmonary valve cusp motion.

## Tricuspid Regurgitation

With TR, there is usually evidence of a right ventricular volume overload pattern, including right atrial dilation. A "B-bump" of the anterior tricuspid leaflet is often noted on M-mode. The tricuspid valve annulus may be dilated (3.4 cm diameter in systole, ≥3.2 cm in diastole). There may be signs of pulmonary hypertension. For regurgitation, there may be an anatomic etiology (e.g., valvular vegetation, ruptured chordae tendineae).

#### Tricuspid Stenosis

With tricuspid stenosis, thickened valve leaflets may be noted. The right atrium is usually dilated as well as the IVC (normal 1.2 to 2.3 cm) on M-mode. There will be decreased tricuspid valve excursion (D–E) and a decreased or absent A wave of the anterior leaflet.

# Color and Doppler Flow Imaging

A complete listing of all of the possible findings and interpretation with color and Doppler flow imaging is beyond the scope of this book. However, there are some rules of thumb:

- Any velocity greater than 2 m/sec in the heart must be explained. Something as simple as a hyperdynamic heart from anemia can cause it; however, pathologic causes should be excluded.
- The Bernoulli equation can be used to determine pressure drops across values:

$$\Delta P \text{ (mm Hg)} = 4 \times [\text{velocity (m/sec)}]^2$$

• An approximation for right ventricular systolic pressure (RVSP) is

RVSP (mm Hg) =  $4 \Delta P$  [tricuspid valve (mm Hg)] + 10 mm Hg

The actual method of calculating RSVP is

RSVP (mm Hg) = 
$$4 \times (TR \text{ peak velocity})^2 + RAP$$

See the "Pulmonary Hypertension" section for estimation of RAP; for most patients, RAP can be approximated at 10 mm Hg.

- Normal aortic and pulmonary valves produce a "bullet-shaped" pattern on spectral analysis. Normal mitral and tricuspid valves produce an "M-shaped" pattern on spectral analysis.
- Laminar flow produces linear spectral analyses, but turbulent flow fills in the area under the curve. Regurgitant flow is always turbulent.
- With color Doppler, a green hue indicates turbulent flow. Highly turbulent flow is mosaic in appearance.

# **COMPLICATIONS**

- Failure to provide an adequate scan
- Failure to diagnose
- Clinical deterioration while scanning in the acute setting

# **CPT/BILLING CODES**

# **SUPPLIERS**

There are several manufacturers with products ranging from the basic to the very sophisticated. Small hand-held machines are now available. Acuson Siemens, Biosound Esaote, General Electric Healthcare, Medison, Phillips, and Toshiba all offer a range of devices from hand-held to research oriented (see the "Suppliers" section in Chapter 172, Obstetric Ultrasounography, for the Internet and mailing addresses as well as the phone numbers for many manufacturers). An excellent way to review the equipment is to visit the company websites. Used equipment is also available, but the cost and inconvenience of service and repairs are often a disadvantage. Over-reading services are also available.

# PULMONARY FUNCTION TESTING

Michael A. Altman

Pulmonary function testing (PFT) is an important tool used by clinicians to evaluate individuals for lung disease. The parameters commonly measured include lung volume, airflow (timed volume), and airway reactivity. As it turns out, clinicians cannot reliably identify obstructive or restrictive patterns from history taking and physical examination alone. In one study, when clinicians were asked to predict the results of PFTs, they correctly predicted an obstructive pattern 83% of the time. However, when predicting a normal or restrictive pattern, they were correct only about half of the time. Besides identifying abnormalities, PFTs allow the severity of an abnormality to be quantified and the amount of reversibility to be determined. This ability to quantify abnormalities also allows a clinician to follow treatment in an objective manner.

A spirogram is a recording of exhaled and inhaled volume (liters) over time (seconds). Spirometric examination is the most widely used tool to assess pulmonary function in office practice. It can be used to evaluate patients suspected of having disease on the basis of clinical findings or to monitor changes in a patient over time. Although formal PFTs are more comprehensive and, if necessary, can provide an objective measure of impairment, spirometry is sufficient most of the time.

In fact, spirometry is underused. Such examinations should be readily available in most medical offices. The National Asthma Education Program (NAEP) recommends an objective measurement of lung function (either spirometry or PFTs) whenever diagnosing or managing asthma. There is evidence that both patients and clinicians have inaccurate perceptions of the severity of asthma in the absence of PFTs, thereby increasing the risk of mortality. The American Thoracic Society (ATS), the European Respiratory Society (ERS), and the Global Initiative for Chronic Obstructive Lung Disease (GOLD) have published guidelines urging the use of spirometry to correctly diagnose chronic obstructive pulmonary disease (COPD). Even the National Committee for Quality Assurance (NCQA), which grades quality of care, lists spirometry use in patients with newly diagnosed COPD as one indicator of clinician performance for the Health Plan Employer Data and Informed Set (HEDIS). Some experts suggest that the use of spirometry should be as common as the use of a blood pressure cuff in a primary care clinician's office, especially for patients with asthma or COPD.

**NOTE:** Although useful information can be obtained from spirometry and PFTs, these physiologic tools alone do not establish a diagnosis. The test results must be carefully correlated with clinical and chest radiographic findings.

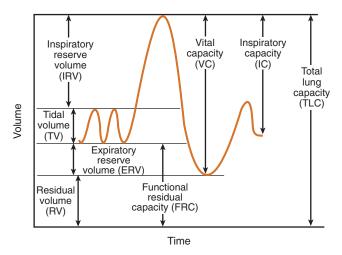

# **DEFINITIONS AND PATHOLOGY**

Common lung volumes measured by spirometry are illustrated in Figure 91-1. The simplest test of lung function is based on a forced expiration. It is one of the most informative tests and requires minimal equipment and calculations. The *vital capacity* is the total volume of gas that can be exhaled after a full inspiration. The vital capacity measured with a forced expiration may be less than that

measured with a slower exhalation, so the term *forced vital capacity* (FVC) is generally used.

Any reduction in FVC affects the ventilatory capacity. The FVC can be affected by conditions affecting the thoracic cage (kyphoscoliosis), diseases affecting the nerve supply to the thoracic muscles, intrinsic diseases of the muscles, abnormalities of the pleural cavity, space-occupying lesions, lung tissue pathology, or stagnation of blood flow in the lungs (as seen in congestive heart failure). In addition, chronic, severe diseases of the airways such as asthma and chronic bronchitis cause peripheral small airways to close prematurely during expiration. This limits the volume that can be exhaled rapidly.

Forced expiratory volume (FEV<sub>1</sub>) is the volume of gas (liters) exhaled in 1 second by a forced expiration from full inspiration. The FEV<sub>1</sub> is affected by the airway resistance of the medium to large airways. Forced expiratory flow (FEF<sub>25%-75%</sub>) is the flow over the middle half of the FVC, the average flow from the point at which 25% of the FVC has been exhaled to the point at which 75% has been exhaled. It is measured in volume (liters) divided by time (seconds). It is the most sensitive office measurement of small airway obstruction or disease. Any increase in airway resistance reduces the ventilatory capacity. Of note, older patients, especially those with obstructive disease, may take a long time to exhale completely for an FVC, as long as 12 to 15 seconds. This is a long time to maintain maximal expiratory effort and may cause discomfort or even lightheadedness. Consequently, certain experts now suggest measuring FEV<sub>6</sub> (forced expiratory volume at 6 seconds) as a substitute for FVC in adults. Subsequently, FEV<sub>6</sub> has been shown to be equivalent to FVC for identifying obstructive and restrictive patterns in adults,

**Figure 91-1** Spirogram showing tidal breathing and the divisions of total lung capacity. The residual volume is measured by indirect techniques. (From Mueller GA, Elgen H: Pulmonary function testing in pediatric practice. Pediatr Rec 15:403–411, 1994.)

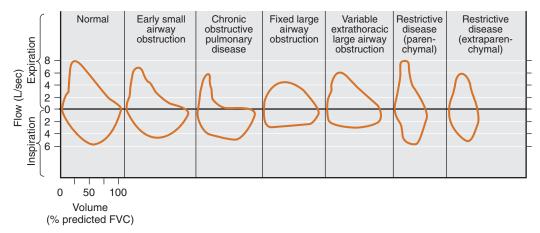

Figure 91-2 Characteristic flow–volume curves of restrictive disease and various types of obstructive diseases compared with normal. The top part of the curve represents maximal forced expiration, whereas the bottom represents maximal inspiration. FVC, forced vital capacity.

and to be more reproducible and less demanding. The flow–volume loop (Fig. 91-2) has two components: the expiratory flow–volume (top half of curve) and the inspiratory flow–volume (bottom half of curve). The top half is where 95% of the information is obtained (expiratory flow).

The inspiratory flow–volume curve is not affected by anything causing dynamic compression of the airways because the pressures during inspiration always expand the bronchi. However, a large (fixed or variable) airway obstruction will cause flattening of the curve because maximal flow is limited. The expiratory flow–volume curve will also be flattened by a fixed large airway obstruction. With restrictive airway disease, the flow–volume curve will be smaller or narrower. One important place to review the inspiratory flow–volume curve is when factitious asthma is suspected. With factitious asthma, there is inappropriate vocal cord closure, also known as vocal cord dysfunction, and although the subsequent wheezing may mimic asthma (or exercise-induced asthma), the inspiratory curve is notched or attenuated, which does not occur in true asthma. With true asthma, only the expiratory curve is usually affected.

The expiratory flow–volume curve may take on different morphologies. Notice how the downward loop becomes more scalloped as airway obstruction increases. However, a large (fixed or variable) airway obstruction will cause flattening of the curve because maximal flow is limited. In restrictive lung disease, the flow–volume curve will be *narrow* (almost up-and-down), with little to no "terminal tail" like that seen with COPD.

Two "pearls" should be borne in mind: (1) examination of the shape of the curve is just as important as the actual numerical data generated by spirometry testing; and (2) restrictive lung disease can be ruled out in 95% to 99% of cases with a normal-appearing flow-volume loop. However, if suspected on clinical grounds, formal PFTs measuring the total lung volumes are indicated. (Spirometry falsely identifies restrictive lung disease in 58% of flow-volume loops that suggest a restrictive defect.)

# **INDICATIONS**

# **Diagnostic Indications**

- To evaluate symptoms, signs, or abnormal results of other diagnostic tests in individuals older than 5 years of age.
  - Symptoms: cough, dyspnea, wheezing, orthopnea, or chest pain
  - Signs: overinflation, expiratory slowing, cyanosis, chest deformity, wheezing, or unexplained crackles
  - Abnormal results of diagnostic tests: hypoxemia, hypercapnia, polycythemia, or abnormal chest radiographs

- To measure the effect of disease on pulmonary function.
- To screen persons at risk for pulmonary disease (e.g., persons with occupational exposure to injurious substances or who have active or passive smoke exposure). The evidence does not support the widespread use of spirometry to improve smoking cessation rates.
- To assess preoperative risk in patients with COPD or asthma. However, there are few published data comparing spirometric data with clinical data for predicting postoperative pulmonary complications in patients undergoing nonthoracic surgery. Hence, even a poor FEV<sub>1</sub> result is not sufficient grounds to withhold surgery in non-thoracic cases.
- To screen patients undergoing lung resection surgery.
- To assess prognosis of lung disease.

#### **Monitoring Indications**

- To assess effectiveness of a therapeutic intervention (e.g., bronchodilator therapy, steroid treatment for asthma or interstitial lung disease). For asthma, according to NAEP guidelines, PFTs are indicated after therapy is initiated and symptoms and peak flow have stabilized, during periods of progressive or prolonged loss of control, and at least every 1 to 2 years.
- To track the course of a disease affecting lung function in patients who identify activity-limiting symptoms, especially when FEV<sub>1</sub> is less than 50% (e.g., obstructive airway disease, interstitial lung disease, or neuromuscular disease, such as Guillain-Barré syndrome).
- To assess current status of persons with occupational exposure to injurious substances.
- To detect adverse reactions to drugs with known pulmonary toxicity.

#### **Evaluation of Disability or Impairment**

- To assess patients as part of a rehabilitation program (e.g., medical, industrial, vocational).
- To assess risks for an insurance evaluation (no evidence of benefit).
- To assess the condition of persons for legal reasons (e.g., Social Security or other program involving government compensation, personal injury lawsuits).

# **Public Health**

- Epidemiologic surveys
- Derivation of normal values for PFTs

# **CONTRAINDICATIONS**

- Severe debilitation and excessive tiring (patients who cannot expend the required effort for testing)
- Severe or moderately severe respiratory distress
- Patients not motivated or desiring to take the test
- Children too young to conduct testing (PFTs are usually helpful
  if the patient is older than 5 years of age; however, some children
  cannot conduct testing adequately until after age 7 years)

## **EQUIPMENT**

- Pulmonary function testing machine/spirometer
- Comfortable chair and private area of office for testing (avoids patient embarrassment)
- Nose clips (soft clips are preferred and recommended to prevent air leaks)
- Various inhalants for testing response to bronchodilators (e.g., albuterol inhaler with 90 µg/puff), if indicated

The office spirometer should conform to minimal requirements or specifications established by the American Thoracic Society (Table 91-1). Not all commercially available spirometers meet these standards. Ideally, the computerized spirometer should have software that allows formulas and algorithms to be modified. Routine preventive maintenance, cleaning, and quality control measures are necessary to ensure accurate results in spirometric testing. Frequent (if not daily) calibration according to the manufacturer's instructions is highly recommended. The spirometer should also be evaluated frequently for leaks. Instructions for maintenance, as well as how to perform tests for quality control, should be provided by the manufacturer. The clinician is responsible for ensuring that the office personnel are trained to carry out the recommended maintenance.

**NOTE:** Peak flow meters are advantageous for patients to use at home, but they do not provide the documentation needed in the office.

#### PREPROCEDURE PATIENT PREPARATION

Before performing a PFT, review the patient's respiratory history, including any medications the patient may be taking for respiratory

problems. A clear explanation of the test and what is to be expected is essential to the patient's performance. The PFT has both an effort-dependent and an effort-independent portion. The best overall result is obtained when the patient gives a maximal effort. Patients with no prior experience with PFTs should make two to three practice attempts until a maximal effort is obtained. A demonstration of the test may be helpful.

Usually the patient is seated to perform the test. The thorax should be erect and the head should be in a neutral position. Explain that this test measures lung function and that the best results are obtained when the patient takes a deep breath and then blows out as hard, as fast, and as long as possible (with the exception of older patients, for whom at least 6 seconds may be necessary to obtain a result [FEV<sub>6</sub>]). Smokers should try to abstain from smoking for at least 1 hour before testing.

# **TECHNIQUE**

- 1. Prepare the equipment to test for FVC. Machine calibration and parameter setups vary between spirometers. See the individual instructions pertaining to the particular instrument for this portion of the procedure.
- 2. Document the patient's position (usually seated). If for some reason the patient is standing, it will increase FVC.
- 3. Have the patient breathe in and out several times with the nose clips in place, to become comfortable.
- Ask the patient to take in as deep a breath as possible, to completely fill the lungs.
- 5. Then have the patient quickly insert the mouthpiece. It should be between the teeth with a tight seal being held around it using the lips.
- 6. Next, have the patient blow out as hard, as fast, and as long as possible (try for at least 6 seconds; Fig. 91-3). Enthusiastically coach the patient to breathe out until the forced vital curve flattens out (usually 5 to 6 seconds).
- 7. When the lungs are completely emptied, have the patient breathe in as deeply as possible, to obtain the inspiratory parameter and complete the evaluation. To follow the diagram (see Fig. 91-1), the patient first takes several normal (tidal) breaths, after which he or she will perform a maximal inspiration to total

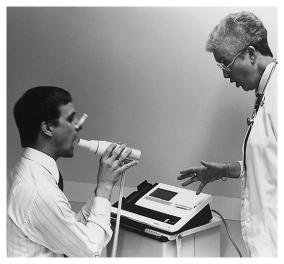

TABLE 91-1	Minimal Recommendations (Specifications) for Diagnostic Spirometry				
Test	Range/Accuracy (BTPS) <sup>†</sup>	Flow Range (L/sec)	Time (sec)	Resistance and Back Pressure	Test Signal
VC	0.5 to 8 L ± 3% of reading or ± 0.05 L, whichever is greater	0-14	30		3-L Cal syringe

FEF, forced expiratory flow; FEV, forced expiratory volume; FVC, forced vital capacity; L/sec, liters per second; MVV, maximal voluntary ventilation; PEF, peak expiratory flow; TV, tidal volume; V, volume; VC, vital capacity.

<sup>\*</sup>Unless specifically stated, precision requirements are the same as the accuracy requirements.

<sup>&</sup>lt;sup>†</sup>BTPS, body temperature pressure saturated (37° C and ambient pressure).

From American Thoracic Society: Standardization of spirometry: 1994 update. Am J Resp Crit Care Med 152:1107-1136, 1995.

**Figure 91-3** Patient takes a deep breath, inserts the mouthpiece, and blows out as fast and as hard as possible.

lung capacity (TLC). The patient then exhales fast and hard, as much as he or she can (FVC or  $FEV_6$ ).

- 8. Repeat the test three times. A minimum of three and a maximum of eight maneuvers are performed until three acceptable curves are obtained. Two or three maneuvers that have values within a 5% difference of each other indicate reproducibility. The best effort is then saved and reported. Acceptability and reproducibility criteria are summarized in Box 91-1.
- 9. If prebronchodilator and postbronchodilator comparison PFTs are needed, administer a short-acting  $\beta$ -adrenergic agonist (e.g., albuterol two to four puffs of 90  $\mu$ g/puff) or other bronchodilator through a hand-held inhaler.
- 10. Wait about 20 minutes for bronchodilation to occur. Then repeat the FVC (FEV<sub>6</sub> for older patients with obstructive disease) for the postbronchodilation measurements, as in steps 1 through 8.

## INTERPRETATION

Some of the factors that influence the normal values of PFTs include the formula used to predict the normal values, test quality, height, age, weight, sex, ethnicity, posture, effort, smoking, and even circadian rhythm. The results and interpretation depend on the clinician paying careful attention to the characteristics of the equipment used, the patient's performance and clinical condition, and the reference values chosen. A patient's own baseline values will provide the best reference data for assessing a patient with chronic pulmonary disease over time.

Interpretation of PFTs can be categorized into three basic patterns: normal function, obstructive, and restrictive (Fig. 91-4). A diagnosis is then made by correlating the test results with the clinical findings from the history, physical examination, and radiographs.

An obstructive process, such as asthma or COPD, is characterized by flow that is low relative to lung volume. Characteristically, timed volume (FEV<sub>1</sub>) and flow (FEF<sub>25%-75%</sub>) are decreased. A decrease in FEF<sub>25%-75%</sub> may detect obstruction in the smaller airways early in the course of the disease, before a change in FEV<sub>1</sub> is evident. This is especially common in smokers, and may be their best early warning before permanent lung damage. A reduction in FEF<sub>25%-75%</sub> from small airway obstruction gives the flow–volume curve a characteristic concave shape. Other causes of small airway obstructive patterns in children include cystic fibrosis, bronchiolitis, bronchiectasis, and heart disease. Causes of large airway obstructive patterns in children

# Box 91-1. Acceptability and Reproducibility Criteria: Summary

#### Acceptability Criteria

Individual spirograms are "acceptable" if

- 1. They are free from artifacts, such as
  - Cough or glottis closure during the first second of exhalation
  - Early termination or cut-off
  - Variable effort
  - Leak
- Obstructed mouthpiece
- 2. They have good starts
  - Extrapolated volume <5% of FVC or 0.15 L, whichever is greater; or
  - Time to peak expiratory flow <120 msec (optional until further information is available)
- 3. They have a satisfactory exhalation
  - Six seconds of exhalation or a plateau in the volume time curve: or
  - Reasonable duration or a plateau in the volume–time curve; or
  - If the subject cannot or should not continue to exhale

#### Reproducibility Criteria

After three acceptable spirograms have been obtained, apply the following tests:

- Are the two largest FVCs within 0.2 L of each other?
- Are the two largest FEV<sub>1</sub> values within 0.2 L of each other?
- If both of these criteria are met, the test session may be concluded.
- If both of these criteria are not met, continue testing until
  - Both of the criteria are met with analysis of additional acceptable spirograms or
  - A total of eight tests have been performed or
  - The patient/subject cannot or should not continue Save, at a minimum, the three best maneuvers.

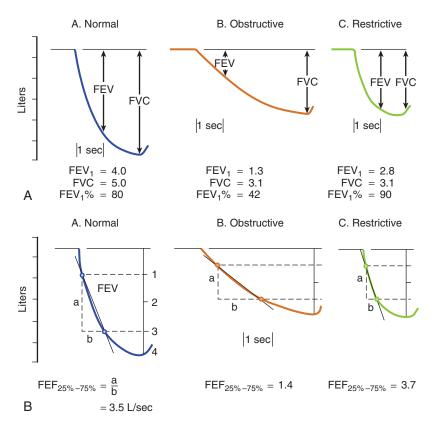

From American Thoracic Society: Standardization of spirometry: 1994 update. Am J Respir Crit Care Med 152:1107–1136, 1995.

include a foreign body, vocal cord dysfunction, vascular rings or laryngeal webs, laryngotracheomalacia, tracheal or bronchial stenosis, enlarged lymph nodes, or tumor. In adults, causes of obstructive patterns include asthma, COPD, congestive heart failure, pulmonary embolism, mechanical obstruction of the airway (benign and malignant tumors), pulmonary infiltration with eosinophilia, vocal cord dysfunction, and cough due to medications (e.g., angiotensin-converting enzyme inhibitors).

Distinguishing between asthma and COPD can be challenging because there can be overlap between the two. However, the following points can be helpful.

#### For asthma

- 1. The history. Diagnosis is typically picked up in childhood (although it can be missed) with cough, wheezing, dyspnea, chest tightness; occurring or worse at night; identifiable triggers (e.g., infections, stress, allergies, changes in weather, strong emotional expression [laughing or crying hard], menstrual periods); a clearly reversible component when a bronchodilator is added (e.g., increase FEV<sub>1</sub> >200 mL, >12% from baseline, or >10% over predicted FEV<sub>1</sub>).
- 2. FEV<sub>1</sub>—the gold standard—<80% if moderate; also, FEV<sub>1</sub>/FVC ratio <80%. In fact, FEV<sub>1</sub>/FVC ratio (i.e., FEV<sub>1</sub>%) is a better measure of asthma severity than FEV<sub>1</sub>.

**Figure 91-4 A,** Normal, obstructive, and restrictive patterns of a forced expiration. **B,** Calculation of forced expiratory flow between 25% and 75% of the FVC (FEF $_{25\%-75\%}$ ). FEV $_1$ , forced expiratory volume at I second; FVC, forced vital capacity. FEV $_1$ % = (FEV $_1$ /FVC) × 100. (From West JB: Pulmonary pathophysiology. In Respiratory Physiology: The Essentials, 6th ed. Philadelphia, Lippincott Williams & Wilkins, 2003.)

For COPD

- 1. The history. Almost always there will be an explanation or cause: to bacco abuse (most common, especially if at least a 20–pack-year history; note, however, that only about 20% of cigarette smokers develop clinically significant COPD),  $\alpha_1$ -antitrypsin deficiency (accounts for 1% of COPD cases; consider if smoking history absent or very early COPD [age <55 years] in smokers), exposure to airway toxins (e.g., industrial chemicals, mineral dust, silica, dust, coal dust, and inhaled endotoxins [e.g., farm worker]).
- COPD-related airflow obstruction is less reversible to inhaled bronchodilator challenges and less variable than asthma.
- 3.  $FEV_1/FVC$  ratio <70% of normal, and  $FEV_1$  <80% of normal.

Postbronchodilator  $FEV_1$  is also recommended for the diagnosis and assessment of severity of COPD.

Low volumes and normal flows characterize a restrictive lung process. The primary criterion for this diagnosis is a reduction in TLC; however, the presence of restriction is commonly inferred from a decreased FVC. It should be kept in mind that a decreased FVC only *infers* a restrictive process because FVC can also be reduced in the presence of airflow obstruction. Significant decreases in FEV $_{\rm l}$  and the FEV $_{\rm l}$ /FVC ratio are key findings that will help differentiate an obstructive from a restrictive pattern when FVC is reduced (see Fig. 91-4A). In addition, when there is both airflow obstruction and reduced FVC, the possibility of restriction can usually be eliminated with evidence of overinflation on the physical examination or a chest radiograph.

Spirometry falsely identifies restrictive patterns in 59% of cases in which FVC was low, consistent with restrictive defect. Unless dictated on clinical grounds, restrictive defects should be confirmed by total lung volume measurements. Measuring TLC requires referral to a pulmonary function laboratory. Measurement of lung volume by helium dilution, nitrogen washout, or body plethysmography can definitively confirm a diagnosis of a restrictive lung condition. Although a reduced TLC defines restriction, measuring FVC has

frequently been demonstrated to be more useful for following the course of the disease process. Restrictive disease is uncommon and can be divided into parenchymal and extraparenchymal etiologies. Parenchymal causes include silicosis, pneumoconiosis, idiopathic pulmonary fibrosis, sarcoidosis, and drug- or radiation-induced interstitial lung disease. Extraparenchymal disease can be due to loss of lung volume (e.g., pleural effusion, pneumothorax), chest wall deformity, extrathoracic compression (e.g., ankylosing spondylitis, ascites, kyphoscoliosis, obesity), or neuromuscular problems (e.g., Guillain-Barré syndrome, myasthenia gravis, muscular dystrophy, cervical spine injury, or diaphragmatic weakness or paralysis). Suspicion of restrictive disease warrants referral. Table 91-2 summarizes the characteristic patterns of obstructive and restrictive lung diseases as measured by spirometry.

Many systems are available to quantify the severity of pulmonary impairment; however, there is currently no universal standard based

TABLE 91-2 Characteristic Patterns of Obstructive and Restrictive Lung Disease as Measured by Spirometry

	Obstruction	Restriction
FVC	Normal or ↓	<b>\</b>
FEV <sub>1</sub>	$\downarrow$	Normal or ↓
FEV <sub>1</sub> /FVC	Normal (early) or ↓	<b>↑</b>
FEF <sub>25%-75%</sub>	↓	Normal, ↑ or ↓

FEF, forced expiratory flow;  $\text{FEV}_{\text{I}}$ , forced expiratory volume; FVC, forced vital capacity.

\*Low flows with normal volumes characterize obstructive disease, whereas normal flows with low volumes characterize restrictive disease. In severe obstruction, gas trapping reduces FVC because of an increased residual volume.

on differences between ethnic populations.\* In practice, severity is usually described as a percentage of either predicted FEV1 for obstructive conditions or predicted TLC for restrictive conditions. ("Normal" predicted test values are obtained by testing a large group of people who have been determined to be free of lung disease.) The test results for a given patient are then expressed as a percentage of the predicted value for age, height, sex, and race. In reality, no one set of equations will be entirely accurate for every person in a given population. For the final report, the ATS recommends that clinicians define the lower limits of normal by using calculations of the lower 95th percentiles (from the specific set of prediction equations that have been selected as standard reference values); these should be recorded, rather than just the percentages of predicted function (e.g., 80% for  $FEV_1/FVC\%$ ). The patient should be comparable in age, race, and sex to the reference population. In computerized equipment, it is essential for population standards to be defined in the software.

Although using percentage of predicted function to evaluate results may not be recommended, some guidelines the clinician can use to get a general clinical picture of pulmonary function follow:

#### Vital Capacity

#### **FVC**

80% to 120% of predicted value
70% to 79% of predicted value
50% to 69% of predicted value
<50% of predicted value

Severe reduction
Severe reduction

Again, restrictive lung disease is characterized by reduced vital capacity and relatively normal airflow rates. If obstruction is present (see "Flow Rates" section), the reduction in vital capacity may only be reported as "probably secondary to obstruction" if the severity of the reduced vital capacity and that of the obstructive findings are approximately equal. In comparing vital capacities obtained at different times (including those obtained before and after bronchodilator administration), the expiratory time must be considered and compared. The raw curves should also be compared.

#### Flow Rates

FEV<sub>1</sub> can be plotted as the percentage of vital capacity [(FEV<sub>1</sub>/FVC)  $\times$  100], or FEV<sub>1</sub>%.

#### FEV<sub>1</sub>%

>75%	Normal
60% to 75%	Mild obstruction
50% to 59%	Moderate obstruction
<50%	Severe obstruction

**NOTE:** For patients less than 25 years old, add 5% to these figures; for those more than 60 years old, subtract 5%.

#### FEF<sub>25%-75%</sub>

>79% of predicted value
60% to 79% of predicted value
40% to 59% of predicted value
40% of predicted value
Vormal
Mild obstruction
Moderate obstruction
Severe obstruction

In most cases of *obstructive* lung disease, the percentage of the predicted value of the  $FEF_{25\%-75\%}$  will be "worse" than the percentage of the predicted value of the  $FEV_1$ . However, the modifier used to describe the type of *obstruction* (i.e., mild, moderate, or severe) should be that associated with the value of the  $FEV_1$ , not the  $FEF_{25\%-75\%}$ . The  $FEF_{25\%-75\%}$  may be separately referred to with such statements as "... particularly affecting small airways, as reflected in

the  $FEF_{25\%-75\%}$ ." Should the  $FEF_{25\%-75\%}$  alone be abnormal, the diagnosis of obstructive lung disease should not be assumed; rather, the reduction should be interpreted as compatible with "early small airways disease." Again, for comparison over time, the raw curves should be examined to determine adequacy of effort.

Therefore, an FEV $_1$ % less than 75% indicates some loss of elastic recoil (e.g., emphysema) or obstructive disease (e.g., asthma), whereas reduced FVC and FEV $_1$  (but FEV $_1$ % >75%) indicates restrictive disease. Again, suspicion of restrictive disease warrants referral.

For the final interpretation, the flow–volume loops can be useful in conjunction with the volume–time spirogram. A flow–volume loop can help determine whether an obstruction is in the larger or the smaller airways. It can also help determine whether a restrictive pattern is due to a parenchymal or an extraparenchymal cause. The most useful information obtained from flow–volume loops is usually in the expiratory portion of the flow loop (see Fig. 91-2). However, flow–volume loops may be derived only if the spirometer is accurate in displacement and time.

# APPLICATION OF SPIROMETRY IN ASTHMA AND CHRONIC OBSTRUCTIVE PULMONARY DISEASE MANAGEMENT

The following flow rates (FEV $_1$ ; from NAEP Guidelines, 2007) can be used to assess asthma:

≥80% Mild asthma (if associated with symptoms)

60% to 79% Moderate asthma ≤60% Severe asthma

Low FEV $_1$  is associated with increased risk of severe asthma exacerbations. However, in children, exacerbations can happen even with normal FEV $_1$ . Consequently, recent emphasis has shifted to FEV $_1$ % (FEV $_1$ /FVC × 100, with levels of impairment listed in the "Flow Rates" section) because it may be a more sensitive indicator of asthma severity. Ultimately, in children and adults, treatment decisions should be based on symptoms and frequency and severity of past exacerbations, combined with PFTs as an additional guide.

Spirometry can also be very helpful in staging COPD severity. More important, it provides a basis for medical decisions based on objective data. Revised guidelines (2006) by GOLD through the National Heart Lung and Blood Institute (NHLBI) and the World Health Organization (WHO) are briefly summarized in Table 91-3.

The  ${\rm FEV_1}$  and  ${\rm FEV_1/FVC}$  data generated in the clinician's office using a spirometer define when to "step up" treatment and which drugs should be used.

# ERRORS AND RULES OF THUMB IN PULMONARY FUNCTION TESTING

Some technical errors and their effects in pulmonary function testing include the following:

- An air leak due to a poorly fitting nose clip or mouthpiece can result in a wandering baseline, which can lead to underestimation of many spirometric measurements.
- An incomplete expiration may give a falsely low reading of FVC and a spurious increase in FEF<sub>25%-75%</sub>.
- Poor initial expiratory effort may give a falsely low reading of the  $FEV_1$  and  $FEF_{25\%-75\%}$ .

PFTs have a false-positive rate of approximately 5%. Borderline values should be interpreted cautiously. In addition to the ranges listed in Table 91-3, the changes in spirometric results over time for an individual can affect the interpretation of the results. The coefficient of variation relates the standard deviation to the main value and is a measure of test-to-test variability in a given individual. The

<sup>\*</sup>There are referenced "normal" data sets now on the Internet for different parts of the world.

over Time	e in Spirom	etric Indexes	5
	Percent Changes Required to Be Significant		
	FVC	FEV <sub>1</sub>	FEF <sub>25%-75%</sub>
Within a Day Normal subjects Patients with COPD	≥5% ≥11%	≥5% ≥13%	≥13% ≥23%
Week to Week Normal subjects Patients with COPD	≥11% ≥20%	≥12% ≥20%	≥21% ≥30%
<b>Year to Year</b> Normal subjects Patients with COPD	≥15% ≥15%	≥15% ≥15%	

COPD, chronic obstructive pulmonary disease; FEF, forced expiratory flow; FEV<sub>1</sub>, forced expiratory volume; FVC, forced vital capacity.

Adapted from American Thoracic Society: Lung function testing: Selection of reference value and interpretive strategies. Am Rev Respir Dis 144:1202–1218, 1991.

interval between tests, the intrinsic variability of the test, and the presence of disease are among the factors that determine the coefficient of variation.

Lung function declines with age. It is estimated that vital capacity decreases 60 mL/year after peaking during young adulthood. Differentiating "real" decline in lung function from expected test variability across time can be difficult. Recommended requirements for significant spirometric changes (normal variability) have been calculated and are listed in Table 91-3.

Adolescents should not be compared with adult standards until growth and puberty are complete. This recommendation is necessary because leg length, thorax height, and total body height proportions change throughout puberty.

Other sources of error include inadequate preventive maintenance of the equipment, inadequate training of the staff, inadequate patient motivation, not correlating the results with the entire clinical picture (e.g., history, physical examination, radiographic findings), and not ordering more definitive tests when the results are unclear (e.g., obtaining a formal TLC measurement when both FVC and flow are reduced).

In the past, when managing patients with COPD, if the  $FEV_1$  went below 1.0 L, the prognosis was thought to worsen dramatically (similar to a cardiac ejection fraction <20%). We now know that patients occasionally can survive for years with an  $FEV_1$  less than 1.0 L if they stop smoking and have a good exercise capacity (e.g., can walk several blocks).

For final values that are confusing or do not make sense (e.g., hyperinflation on chest radiograph and abnormal PFTs, yet no history of smoking and no other risk factors for COPD), cardiopulmonary exercise testing (expired gas exercise testing) may be helpful. In addition, one of the most common causes of emphysema (or premature emphysema in nonsmokers) is  $\alpha_1$ -antitrypsin deficiency. This tends to run in families and can be excluded by a simple blood test that many laboratories perform.

# **SCLEROTHERAPY**

Jerry Ninia

Sclerotherapy is a technique used to eliminate unwanted veins (both varicosities and spider veins). This is accomplished by injecting a noxious agent into the lumen of the vein, which causes destruction of the endothelium with an inflammatory response. When used with compression, it results in obliteration of the vessel. The goal of treatment is to eradicate abnormal veins while preserving healthy veins.

# **BACKGROUND**

Ancient physicians, scholars, and poets, including Hippocrates and Homer, recognized varicose veins. Improvements in syringes and needles and the development of more effective and safe sclerosing solutions allowed sclerotherapy to become a modern and effective method of treatment. Clinicians now use sclerosants developed in the 20th century (e.g., hypertonic glucose, hypertonic saline, sodium morrhuate, chromated glycerin, ethanolamine oleate, and stabilized polyiodide iodine). However, the most popular agents used in sclerotherapy are sodium tetradecyl sulfate (Sotradecol), polidocanol (Aethoxysklerol), and hypertonic saline (Table 92-1).

Organizations worldwide—including the American College of Phlebology and the American Venous Forum in the United States—have been formed to further research and education in venous disease. Recently, the American Medical Association has recognized phlebology as a separate and distinct medical specialty.

# **ANATOMY**

The venous system is divided into three levels: *deep*, *perforating*, and *superficial* veins. The veins treated with sclerotherapy are the perforating and the superficial veins.

Deep veins are encased in fascia and muscle. In ascending order, they are the anterior and posterior tibial veins, the peroneal vein, the tibioperoneal trunk, the popliteal vein, the superficial femoral vein, the deep femoral vein, the common femoral vein, and the iliac vein. These veins convey blood from the lower limb back to the heart (Fig. 92-1).

The superficial venous system is confined to the veins above the fascia in the subcutaneous tissue and involves the great and small saphenous veins and their tributaries, in addition to the lateral subdermal veins (of Albanese) around the knee (Figs. 92-2 and 92-3).

Approximately 150 perforating veins connect the superficial and deep systems. Many of these veins are eponymous with the anatomists who demonstrated them (Fig. 92-4). In the middle area of the thigh are the Hunterian perforators, and in the distal thigh are the Dodd perforators. These veins connect the thigh portion of the great saphenous vein to the femoral vein. Below the knee is Boyd's perforator, connecting the great saphenous vein to the popliteal vein. The infrapopliteal perforating veins along the medial aspect of the leg connect a major branch of the saphenous vein, the posterior tibial arch vein, to the posterior tibial vein.

There are also important perforating veins along the posterior aspect of the calf, which connect the small saphenous system to the tibial venous system, and perforators along the lateral aspect of the knee that connect the lateral subdermal plexus of Albanese to the deep venous system.

There are several important connections from the superficial venous system to the deep femoral vein. The posterior thigh perforator connects the superficial veins of the posterior thigh to the deep femoral vein. In addition, the inferior gluteal vein and the veins of the medial thigh connect through the internal pudendal system to the deep pelvic veins. It is the latter system that results in the vulvar varicosities seen frequently in pregnancy. Although it is not necessary to remember all of the proper names of these perforators, it is important for the clinician to have knowledge of their location so that sclerotherapy can be carried out in a logical and effective manner.

In general, unwanted veins are referred to as telangiectases, reticular varicosities, or varicose veins (Table 92-2).

#### **PHYSIOLOGY**

#### **Primary Varicose Veins**

The veins of the lower limb carry blood against the force of gravity back to the heart. This is accomplished by two principal means. When the muscles of the calf contract, they compress the soleal sinuses and the deep veins encased in fascia and muscle, achieving a pressure of up to  $300~\rm cm~H_2O$ . Because the veins of the lower limb have valves that allow blood to flow only in a proximal direction, the column of blood is forced into the valveless veins of the abdomen

If a person is standing still, the pressure of the veins on the dorsum of the foot will equal the distance from the foot to the right heart. This results in an average pressure of approximately of 70 to 80 cm  $\rm H_2O$ . As evidenced by the pressure relationship mentioned previously, the pressure exerted by the contraction of the calf muscles is sufficient to overcome the effects of gravity and propel blood in a proximal direction. The flow of venous blood from the calf back to the heart may be considered the systolic phase. During this phase, blood is prevented from going into the superficial venous system by the valves of the perforating veins. During the relaxation phase, when the pressure in the calf compartment is diminished, blood can flow from the superficial veins through the perforators into the deep veins. Therefore, the superficial venous system may be likened to an atrium of the heart, and the deep veins of the calf may be likened to a ventricle.

This physiologic system breaks down when the walls of the veins dilate, causing the valves to become incompetent. The manner in which veins become incompetent is somewhat controversial. The belief has been that the problem is initiated by a malfunctioning valve. The incompetent valve allows blood to flow in a reverse direction as gravity pulls it down toward the foot. The resulting increase in venous pressure causes the veins to dilate and

TABLE 92-1 Most Common Sclerosing Agents in the United States						
Agent	Food and Drug Administration Approval	Supply	Maximum Dose Per Visit	Indications	Companies	Comments
Sodium tetradecyl sulfate (Sotradecol, STS)	Yes	2-mL ampules (1%, 3%)	10 mL 3% solution	0.1%-0.25% up to 2 mm; 0.25%-0.5% reticular; 0.5%-1% <4 mm; 1%-3% >4 mm	Elkin-Sinn, Inc. (Cherry Hill, NJ); Wyeth-Ayerst (Philadelphia, PA)	Painless; can cause extravascular necrosis
Hypertonic saline	Yes, as abortifacient	30-mL ampules (23.4%); dilute as needed with lidocaine 1% (may be stored dilute for up to 12 wk)	10 mL; more can cause leg cramps, significant salt load	11.7% <2 mm (especially for matting); 23.4% >2 mm (many use the 18.7% solution for all vessels; see text)		Major advantages: no anaphylaxis and inexpensive; some discomfort on injection
Polidocanol (Aethoxysklerol)	No	2-mL and 30- mL ampules (0.5%, 1%, 2%, 3%)	2 mg/kg	0.25%–1% telangiectases and reticulars <4 mm	Kreussler & Co. (Wiesboden- Bielsrich, Germany)	Painless; less extravascular necrosis; need to have compounded or obtain out of United States

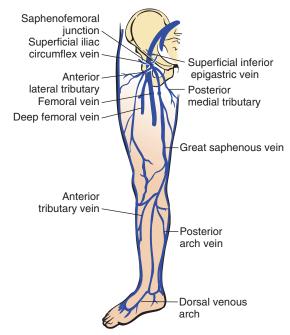

sequentially creates incompetence in the more distal valves. Although this incompetence still may occur, especially in patients who have had phlebitis, which can destroy the valve structure, it now seems likely that in patients who develop primary varicose veins the initiating event is dilation of the vein itself.

The most proximal valve of the superficial system is at the saphenofemoral junction. This valve normally allows blood to flow from the great saphenous vein into the common femoral vein. When this valve becomes incompetent, blood will flow from the common femoral vein into the great saphenous vein, causing progressive dilation of the saphenous vein. This dilation can affect more distal valves, causing them to become incompetent; thus a cycle is begun that eventually causes dilation of the entire saphenous system.

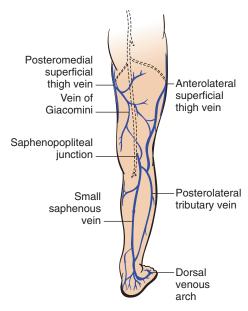

Inferior vena cava Aorta and common iliac arteries Common iliac vein External and internal iliac veins Common femoral veins Deep femoris vein Femoral veins Veins fromgastrocnemius muscle Popliteal veins Soleal vein sinus Posterior tibial veins Anterior tibial veins Peroneal vein

**Figure 92-1** Main venous conduits formed by the deep veins of the lower limbs; numerous branch veins join these.

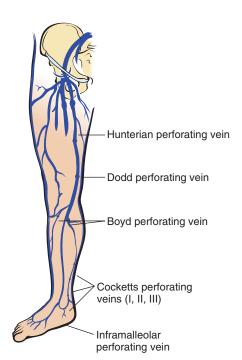

Another mechanism for the development of varicose veins is incompetence of the perforating vein valves. When the calf muscles contract, blood is prevented from flowing through the perforating veins into the superficial system by closure of their valves. If a valve is not working properly, blood will flow from the deep veins into the superficial venous system. The flow of blood from the deep system into the superficial system diminishes the blood flow back to the heart, and it greatly increases the venous pressure in the leg. This increase of the venous pressure, termed *venous hypertension*, is the

**Figure 92-2** Normal anteromedial superficial venous anatomy is depicted. The great saphenous vein ascends from the dorsal venous arch and dominates the anteromedial superficial drainage system. It receives the posterior arch vein (vein of Michelangelo). It also receives variable anterior and posterior tributary veins in the anteromedial calf just below the knee. As the saphenous vein reaches its termination, it receives important tributaries medially and laterally. These tributaries are commonly visualized in duplex ultrasonographic examinations, which may identify reflux in one or both of these vessels.

**Figure 92-3** The small saphenous vein dominates the posterolateral superficial venous drainage. It originates in the dorsal venous arch; at the posterolateral ankle, it is intimately associated with the sural nerve. Note the important posterolateral tributary vein and the posterior thigh vein, which ascends and connects the small saphenous venous system with the great saphenous venous system. The anterolateral superficial thigh vein and the posterolateral tributary vein can be very important in congenital venous anomalies, such as Klippel-Trénaunay syndrome.

**Figure 92-4** Locations of the most important perforating veins associated with the great saphenous system are shown. Note that the Cocketts and inframalleolar perforating veins are actually separate from the great saphenous system. The Boyd perforating vein is constantly present, but it may drain the saphenous vein or its tributaries. Perforating veins in the distal third of the thigh are referred to as *Dodd perforators*, whereas those in the middle third of the thigh are referred to as *Hunterian perforators*.

TABLE	TABLE 92-2 Vessel Classification						
Туре	Vessel Classification	Characteristics	Color				
1	Telangiectases ("spider veins")	0.1-1 mm	Red				
la	Telangiectatic matting	<0.2 mm, very fine; can occur after injection or surgery	Red				
ll .	Venulectasia	I–2 mm	Violaceous				
III	Reticular veins	2–4 mm	Blue				
IV	Nonsaphenous varicosities (second- degree incompetent perforators)	3–8 mm	Blue				
V	Saphenous varicosities	7–8 mm	Blue

cause of many of the sequelae seen in chronic venous insufficiency, such as edema, stasis dermatitis, pigmentation from hemosiderin, and ultimately the development of lipodermatosclerosis and venous ulceration.

# **Secondary Varicose Veins**

Secondary varicose veins can occur as a result of a superficial or deep venous thrombosis (DVT) or from an arteriovenous fistula with resulting high venous pressure. All of these conditions may cause venous dilation and lead to valve incompetence.

#### **INDICATIONS**

- Small, bulging varicose veins up to 0.6 cm in diameter (some phlebologists treat larger veins)
- Venulectasia
- Telangiectasia (commonly called spider veins)
- Pain, itching, burning, tiredness, and heaviness in the lower limb (previously mentioned indications, regardless of size, may cause these symptoms)
- · Cosmesis in the absence of other symptoms
- Venous stasis ulcer
- Venous stasis pigmentation
- Recurrent bleeding of a vessel of any size

Injection of facial telangiectases has been done and reported. It is efficacious. However, venous sinus thrombosis (in the brain) has occurred. Radiofrequency ablation or various laser/light methodologies are often as helpful without the associated risks.

# **CONTRAINDICATIONS**

- Saphenofemoral junction or saphenopopliteal junction reflux.
- Reflux from deep system into superficial creates high venous pressure, making it difficult to obliterate vein.
- Veins larger than 0.6 cm in diameter.
- If the vein has a large diameter, it is difficult to obtain coaptation
  of intimal surfaces for permanent obliteration; it is more likely
  that a thrombus will develop within the lumen of the vein and
  recanalize over time.
- Some practitioners do inject these large vessels, but recurrence and complications are more common and phlebectomy might be a wiser choice of treatment.
- Arterial insufficiency.
- Ankle-to-brachial index less than 0.7 or other signs of inadequate arterial flow.
- Diabetic neuropathy.
- Acute superficial or deep thrombophlebitis.

- Massive obesity.
- Anticoagulation.
- Obstruction of the deep venous system.
- Severe systemic disease (especially collagen vascular disease, malignancy, or severe cardiac problems).
- Pregnancy.
- Lack of mobility, such as seen in stroke, arthritis, or other musculoskeletal disorders.
- Unwillingness to comply with a program of compression.
- Acute febrile illness.

**NOTE:** The clinician should use caution in patients with asthma or numerous allergies (unless hypertonic saline is used) to avoid potential hypersensitivity. Age is not a contraindication if the patient is active and has reasonably good skin turgor.

# **EQUIPMENT**

- Camera for pictures (optional).
- Examination table. (A power table is helpful but not mandatory.)
- Patient stand. (The examination can be performed more optimally if the patient's feet are 24 inches off the floor. Usually this requires a made-to-order stand that includes a strong railing. The stand can be used for both examination and treatment.)
- Good lighting. (A gooseneck lamp is sufficient; however, some therapists use a more intense light source, such as a headlamp.)
- Magnification loupes (3×).
- Syringes (3.0 and 1.0 mL); 1/2-inch, 30-gauge needle.
- Handheld Doppler probe.
- Sclerosing solution:
  - Sodium tetradecyl sulfate (preferred by the author) in dilutions of 0.2%, 0.5%, 1.0%, and (rarely) 3.0%.
  - Hypertonic saline in a dilution of 18.7% is also commonly used (and preferred by the editor). It can be prepared by injecting 2 mL of 2% lidocaine into a 30-mL, multiple-dose vial of 23.4% saline (0.5 mL of this solution is injected per site). It is sterile and can be left diluted for up to 12 weeks.
  - Polidocanol is another common sclerosant but is not approved by the U.S. Food and Drug Administration (FDA).

NOTE: The assistant should have 5 to 10 1-mL syringes drawn up for use, depending on the sclerosant and the quantity of veins to be injected. Each agent has benefits and risks. Hypertonic saline is effective and there are no allergic reactions; however, it is painful and the risk of extravasation necrosis of the skin is significant (Box 92-1). Polidocanol (0.05% to 3%) is a weak sclerosant, but it works well on small veins. Allergic reactions are possible but rare, and it is not FDA approved (in phase III trials). However, it is frequently used in the United States even now (Box 92-2 and Table 92-3). Sodium tetradecyl sulfate is medium in potency and relatively painless, but it must be injected carefully to avoid skin necrosis. Allergy and anaphylaxis can occur, although this is rare (see Table 92-1).

# Box 92-1. Hypertonic Saline Description

True allergic reactions are nonexistent, but side effects are more common.

The degree of endothelial damage is directly proportional to the concentration used.

Dilution with heparin or anesthetics can decrease effectiveness, depending on amounts.

It destroys all cells: endothelium and red blood cells (RBCs). Significant extravasation can produce cutaneous necrosis. Hemolysis of RBCs can cause cutaneous hemosiderin staining.

# Box 92-2. Polidocanol Description

Polidocanol was originally developed as a topical anesthetic under the trade name Sch 600.

There are three groups of local anesthetics:

- 1. Esters: procaine, benzocaine, tetracaine
- 2. Amides: lidocaine, prilocaine, mepivacaine, procainamide, dibucaine
- 3. Urethane: polidocanol

It is generally classified as a weak detergent solution.

It should be diluted with distilled sterile water.

Patients should be warned about an Antabuse–alcohol reaction.

Elimination half-life is 4 hours, with 90% elimination within 12 hours; it does not cross the blood–brain barrier. Injection is painless and cutaneous necrosis difficult to produce.

- Cotton balls with isopropyl alcohol or benzalkonium chloride (Zephiran).
- Tape (1 inch wide). (Some patients require paper tape.)
- Compression stockings. Some clinicians stock them in the office. Patients can also be given a prescription to purchase them at a medical supply store (with proper measurements noted on the prescription) or they may be fitted at certain retailers. Pantyhose, full-length stockings, thigh-high stockings, or calf-high stockings are selected based on the areas being injected. Rubber gloves are helpful to apply the stocking(s).
- Elastic wraps (4 to 6 inches wide; e.g., Ace bandages).
- Nonsterile gloves.

**NOTE:** Additional instruments that may be helpful, but not necessary, include a photoplethysmograph, light reflection rheograph, and a duplex scanner. Duplex ultrasound has become very important in phlebology, especially in the proper evaluation and treatment of patients with advanced venous disease.

# PREPROCEDURE PATIENT PREPARATION

It is best if the patient receives patient education materials before the office visit (see the patient education handouts online at www. expertconsult.com). An initial visit is scheduled for 30 minutes. The patient is evaluated, venous testing is done, the legs are measured for hose, and counseling is completed. Future visits of 15 to 30 minutes are scheduled for the injections at 2- to 4-week intervals. It is best not to reinject the same area any sooner than 3 to 4 weeks. Average patients will require three 30-minute injection visits.

A careful history and physical examination must be performed (Fig. 92-5), and those problems that might affect treatment with sclerotherapy (e.g., anticoagulation, history of phlebitis, vein surgery, arterial disease, bleeding problems, diabetes, history of severe allergic reactions) should be sought.

Physical examination must include a careful evaluation of the pedal pulses. If they are not readily felt, it is necessary to obtain an ankle-to-brachial index. The only equipment needed for this is a blood pressure cuff, stethoscope, and handheld Doppler probe.

**TABLE 92-3** Maximum Daily Doses of Polidocanol

	Dose (m	Dose (mL) According to Body Weight of Patient					
Concentration	50 kg	60 kg	70 kg	80 kg	90 kg		
0.5% 1.0% 2.0% 3.0%	20 10 5 3.3	24 12 6 4	28 14 7 4.6	32 16 8 5.3	36 18 9 6		

It is essential to look for the presence of saphenofemoral or saphenopopliteal reflux, also known as axial vein reflux. Its presence is a contraindication to sclerotherapy, and many insurance companies will not cover sclerotherapy if it is present. This determination can be accomplished with a careful hand-held Doppler examination. The patient must be standing. The tip of the Doppler probe is held at the saphenofemoral or saphenopopliteal junction while the calf muscle is firmly and sharply compressed. This creates a sound when the blood is propelled forward. As the muscle is released, there should be no retrograde flow (only silence). If flow is heard, it means there is reflux at these junctions. Newer techniques are indicated, including saphenous vein ablation with a radiofrequency or laser catheter (see Chapter 54, Lasers and Pulsed Light Devices: Leg Telangiectasia).

Patients are often screened with photoplethysmography (PPG) and light reflection rheography. These are means of measuring the venous refilling time of the lower limb using a transducer to shine a certain wavelength of light into the skin about 10 cm proximal to the medial malleolus. Hemoglobin specifically absorbs this wavelength. With the patient seated, he or she dorsiflexes the foot 8 to 10 times. This compresses and empties the normal dermal venous plexus. The light that is not absorbed by hemoglobin is reflected back to the transducer and is measured. This reflection back is greater when the veins are empty (less hemoglobin to absorb the light) and decreases when the veins are full because the vessels filled with blood (hemoglobin) absorb more light. The instrument then records how long it takes for the blood of the dermal plexus to return to baseline. A refilling time of less than 25 to 30 seconds indicates that the venous plexus is filling partially in a retrograde fashion and demonstrates incompetence of the venous system. If the test result is abnormal, a tourniquet should be applied just above and then below the knee. The test is repeated; if values normalize, it suggests that the problem is within the superficial venous system (Figs. 92-6 through 92-8) and that sclerotherapy can proceed. If the filling time does not normalize with above- and below-knee tourniquets, it suggests deep venous insufficiency and further evaluation (i.e., duplex ultrasonography) may be indicated.

PPG findings have been found to correlate well with venograms for the determination of DVT. In this instance, outflow of blood is blocked, and thereby the tracing is flat.

A duplex scan performed when the patient is standing allows an estimate of the location of venous reflux and its magnitude. The clinician can also look for DVT, venous obstruction, and incompetent perforators. Duplex ultrasound has emerged as the most reliable, cost effective, reproducible way to evaluate the lower extremity venous system. In recent years, units have become less expensive and training in ultrasonography is available.

Photographs of the lower limbs may be necessary. Some insurance companies require them. More important, photographs provide baseline information to which the patient's limbs can be compared as treatment progresses. Many phlebologists first draw the veins in on diagrams.

The technique of sclerotherapy must be carefully explained to the patient, including possible complications and what will happen over the course of treatment. The patient must be cautioned not to expect perfection. A well-educated patient is more cooperative and satisfied.

# **TECHNIQUE**

Before injecting the patient, obtain a signed consent (see the sample patient consent form online at www.expertconsult.com).

Wipe the area to be injected with Zephiran or alcohol. This not only cleanses the area but improves visualization of the vessels. Use a small syringe (1 or 3 mL). Stretch the skin surrounding the vessel with the nondominant hand. It is helpful to bend up the tip of the 30-gauge needle about 20 to 30 degrees to cannulate these tiny veins (Fig. 92-9).

Direct cannulation of the vein is absolutely essential. Extraluminal injections may lead to skin necrosis. For the treatment of veins 2 mm in diameter or less, 0.2% sodium tetradecyl sulfate is used. Although some therapists suggest a concentration of 0.1%, it is not necessary to decrease the concentration (Table 92-4, p. 615). Aspiration of blood from the small vessels cannot be accomplished. If a small wheal forms at the time of injection, the needle is not in the lumen and injection must be stopped. If the needle is properly inserted, the vessel should blanch. Once the blanching stops, withdraw the needle and go to the next vessel. More is *not* better unless new vessels continue to blanch. The injection is carried out with extremely gentle pressure, and only 0.1 to 0.3 mL is used. Too much pressure can rupture the vein and lead to unnecessary inflammation.

For injection of veins 3 to 5 mm, 0.5% sodium tetradecyl sulfate is used in a quantity of 0.5 mL to a maximum of 1.0 mL. Because a stronger solution is being used, it is more likely that subcutaneous injection may lead to tissue necrosis. Therefore, aspiration of blood into the hub of the needle is recommended before the injection of sclerosant.

For veins 5 to 6 mm in diameter, 1.0% sodium tetradecyl sulfate is used with a volume of 0.5 mL to a maximum of 1.0 mL (see Table 92-4). Aspiration before injection is essential.

All of the previously mentioned procedures can be performed with the patient supine. Spider veins will remain visible, but at times it may be difficult to cannulate large veins in a supine patient because the veins are not dilated and collapse when the patient lies down. In this case the patient should be asked to stand and the vein cannulated with a no. 27 butterfly that is taped in place. The patient can then be placed in a supine position and the vein injected as previously described. Alternatively, the veins are marked with a skin-marking pen in the standing position and can be injected when the patient lies down.

A compression dressing consisting of a folded piece of gauze is placed over each site and covered with a piece of Dermicel or similar tape. Paper tape is necessary for some patients to avoid allergic responses. A cotton ball and tape are used by many phlebologists and work well. The limb is then compressed either by elastic wraps or compression stockings, as discussed in the section on Compression.

**NOTE:** It is often quicker and easier to just wrap Coban or Co-Flex around the entire leg, followed by the compression hose. This keeps the blood off the hose and makes it easier to get the hose on the leg. These rolls are 4 inches wide and 9 yards long.

A complete note should be dictated (or a form used) for at least the first injection visit (Fig. 92-10, p. 616). After this, we recommend flow sheets to save time (Fig. 92-11, p. 617).

## **PEARLS**

Injection sclerotherapy using hypertonic saline solution or sodium tetradecyl sulfate is a safe, relatively painless method of ablating small varicose veins, reticular venules, and spider telangiectases, with a minimum of complications. The attending physician will have better results and happier patients if several important concepts are remembered:

- Although spider veins may be symptomatic, most patients seek treatment because they are unhappy with the appearance of their legs. The clinician should be cautious and conservative to avoid creating a blemish worse than what the patient already has.
- Sclerotherapy should be viewed as a semicosmetic procedure, and the patient's expectations must be carefully considered.
- Careful preinjection discussion of risks must occur with patients so that they are fully aware of the protracted and tedious nature of sclerotherapy, as well as the potential complications.
- The effect of gravity and incompetent venous valves must always be remembered. Varicose veins and spider veins tend to

recur. The wearing of compression stockings in the immediate postinjection period is mandatory. Compression stockings worn on a long-term basis will significantly reduce recurrence.

- Meticulous technique is essential in sclerotherapy.
  - The clinician must be sure the needle is in the vein.
  - The solution should be injected slowly.
  - A maximum of 0.5 mL of solution should be used per injection, and large bolus injections should be avoided.
  - The clinician should watch the needle tip and stop injecting if there is any extravasation.
- The larger vessels should be injected first.
- The clinician should begin injections proximally and work down the leg. If injections are started distally, the proximal vessels often go into spasm and it is very difficult to inject them.
- Telangiectases will be visible when the patient lies down, but varicosities may disappear. It helps to mark them with a marking pen while the patient is standing.
- The clinician should not attempt to withdraw blood before injecting telangiectases; however, it is essential to withdraw blood before injecting larger vessels to be sure the needle is in the lumen.
- If a wheal is seen, the clinician should stop injecting immediately.
   The magnification loupes help identify this early in the procedure. If recognized early and the injection is stopped, the small

blebs that occur generally do not lead to any tissue necrosis. Older texts recommended diluting the area with saline for extravasation, but it is not needed with these small amounts.

**NOTE:** With careful and precise technique, the majority of small telangiectatic (i.e., spider) veins can be eliminated. Patient satisfaction with the procedure is high.

#### **COMPRESSION**

The amount and duration of compression used with sclerotherapy remain somewhat controversial. Initially, Irish sclerotherapists who were treating large, bulging varicose veins used 6 weeks of continuous compression, a regimen quite difficult for the patient. Later studies suggested that 3 weeks of compression for large veins is adequate. Whether this should be used for 24 hours a day or only while the patient is standing is still an unsettled issue.

When injecting spider veins, elastic compression bandages (4 inches wide) can be used for the first 24 hours. The patient then removes the elastic bandage and the underlying dressings and wears lightweight, measured compression pantyhose (15 mm Hg–gradient hose). Many therapists use 20 to 30 mm Hg–gradient hose or even 30 to 40 mm Hg–gradient hose. The patient is asked to wear the hose during the course of treatment whenever he or she is out of

bed. If the patient has sclerotherapy appointments every 2 to 3 weeks, for example, and requires three visits, the patient will wear the stockings for 9 or 10 weeks. After the last treatment, the clinician can suggest that the patient wear the stockings while out of bed for at least 10 more days (preferably for 3 weeks). A recent review confirmed that wearing support hose continuously for 3 days, then while ambulatory for 3 more weeks, markedly reduced complications and recurrence.

When larger veins are injected, 30- to 40-mm Hg–gradient compression hose are recommended. The type of stocking depends on the areas being injected. If the thighs and both lower limbs are involved, panty hose are best. Otherwise, a full-length stocking, thigh-high stocking, or calf-high stocking can be used if it compresses the areas that were injected. The physician can prescribe the stocking at the time of the patient's initial visit and the patient can then bring it to the first therapeutic session. Many of the stocking

**Figure 92-6 A,** Photoplethysmography (PPG) machine. **B,** PPG machine attached to a patient. (*Author's note*: PPG has been important in the vascular laboratory, but in a clinical setting PPG has been largely replaced by duplex ultrasonography.)

**Figure 92-7** Tracings of photoplethysmography (PPG) readings. **A,** Normal. After dorsiflexing the foot 10 times, the blood has been "squeezed out" of the ankle, so less light is absorbed and more is reflected back. This gives a higher reading. As the veins refill with blood, more light is absorbed so less is reflected back. Thus, a lower amplitude is recorded. A refill time over 25 seconds is normal. **B,** Abnormal. Rapid refill indicating venous insufficiency. Refill time is only 15 to 17 seconds. (Without tourniquets, this could be deep or superficial; if tourniquets are in place, this is most likely indicative of deep venous insufficiency.) **C,** Abnormal. No indication of emptying, suggesting deep venous obstruction or marked insufficiency ("picket fence" pattern).

companies are quite good in supplying physician's offices with stockings and providing prompt, next-day delivery service. Ancillary personnel can learn to measure the patient for ready-made or custom stockings. The patient may then receive the stockings from the physician's office.

It is recommended that patients wear lightweight compression pantyhose as much as possible on an indefinite basis to diminish the recurrence of varicose veins or the development of new ones; however, many patients are resistant to such a regimen. Compression stockings are also used in the management of patients with post-thrombotic syndrome, healed venous ulcers, lymphedema, and other problems. Although patients can purchase cheaper over-the-counter hose, these generally provide only uniform compression and not a gradient of more to less pressure as the hose goes up the leg.

#### **COMPLICATIONS**

 Bruising. Patients must understand that they will look worse before they look better. It may take 4 to 8 weeks before the postsclerotherapy changes have resolved.

**Figure 92-8** Placement of tourniquets above and below the knee when the photoplethysmogram is abnormal. If the tracing normalizes, it indicates superficial venous incompetence. If it remains abnormal with rapid refilling, deep venous insufficiency is suggested.

- Hemosiderin staining (hyperpigmentation). This occurs transiently in almost every case. It is considered a complication when it lasts for more than several weeks. In about 5% to 10% of patients, it can take up to 1 year to diminish. The discoloration follows the outline of the previously injected vein and can also be seen after stripping or phlebectomy. The larger the vein, the more likely it is to occur—especially if compression hose are not worn long enough. Unfortunately, in spite of trying many bleaching creams, little can be done to hasten resolution. If clots are evident, their removal lessens the duration of pigmentation. Prevention (with the use of compression hose) is the key.
- Matting (neoangiogenesis). This is the development of tiny vessels
  at or near the site of previous injection and occurs in 3% to 10%
  of patients. It may result from an injection under too high a pressure (causing rupture of the vessel) or because either the volume
  of the sclerosing solution was too large or the solution was too
  strong. Matting probably develops as part of the inflammatory
  response that occurs as the result of these errors in technique.

**Figure 92-9** Proper injection technique. The nondominant hand stretches the skin around the vessels. The needle bevel is up and the needle itself is bent 30 degrees upward. (Redrawn from Sadick NS: Manual of Sclerotherapy. Philadelphia, Lippincott Williams & Wilkins, 2000.)

Vessel	Solution/Concentration	Volume (per Injection Site)
Telangiectatic matting (after previous treatment)	Hypertonic saline, 11.7% Sodium tetradecyl sulfate, 0.1% Polidocanol, 0.25% (Go slow with low injection pressures)	0.1–0.2 mL
Telangiectasia (up to 1 mm)	Hypertonic saline, 11.7%† Sodium tetradecyl sulfate, 0.1%–0.2% Polidocanol. 0.25%	0.1–0.3 mL
Venulectasia (I–2 mm)	Hypertonic saline, 11.7%–23.4% <sup>†</sup> Sodium tetradecyl sulfate, 0.1%–0.25% Polidocanol, 0.5%–0.75%	0.2–0.5 mL
Reticular veins (2–4 mm, subcutaneous blue veins)	Hypertonic saline, 18.7%–23.4% <sup>†</sup> Sodium tetradecyl sulfate, 0.33%–0.5% Polidocanol, 0.75%–1.5%	0.5 mL (may increase to 1 mL if filling of reticular vein is observed)
Nonsaphenous varicose veins (3–8 mm)	Hypertonic saline, 18.7%–23.4% Sodium tetradecyl sulfate, 0.5%–1.0% Polidocanol. 1.0%–3.0%	0.5 mL (may increase to 1 mL per injection site in large-capacity vein)
Saphenous varicose trunks (usually >5 mm)	Hypertonic saline, 18.7%–23.4% Sodium tetradecyl sulfate, 1.0%–3.0% Polidocanol, 3.0%–5.0%	0.5 mL (low-volume injection critical at high concentrations)

<sup>\*</sup>Solutions in **bold** approved by the U.S. Food and Drug Administration.

However, even with excellent technique, matting may occur. It may disappear in a few months. If it does not, the clinician should make a very careful search for a reticular vein leading into the area and try to obliterate it. Sometimes the matting itself can be injected or treated with light therapy, such as PhotoDerm or laser. If reinjection is done, the clinician should use low concentrations of sclerosants and inject slowly.

- Skin slough with ulceration. Usually this is related to extravasation of the solution. It may occur because of improper placement of the needle, rupture of the vein, having only part of the needle in the lumen, or injection of an arteriole. A tiny arteriole may also connect to a vein. In these cases, closure of the arteriole can cause a skin infarct. Ulcerations can even occur with a perfectly performed injection when the solution erodes through the wall of the vein into unhealthy skin. The ulceration often takes 4 to 8 weeks to resolve.
- Arterial injection. This is a dreaded complication. It will result in
  a large slough and even limb loss if a large artery it is injected. It
  is more likely to occur around the ankle, especially in the area of
  the posterior tibial artery.
- Syncope. This is more common if injections are done with the
  patient standing. At times standing is necessary when inserting
  butterfly needles; then have the patient assume a recumbent position for the injection of large veins.
- Allergic reaction. This will not occur with hypertonic saline, and it occurs extremely rarely with sodium tetradecyl sulfate (approximately 0.3%). When it does occur, it is usually a mild response, although anaphylaxis has been reported. Necessary equipment to treat this problem, such as an Ambu-bag, artificial airways, epinephrine for injection, steroid for injection, and an injectable anticonvulsant should be on hand (see Chapter 220, Anaphylaxis). Pretreatment of allergic patients with 50 mg of diphenhydramine (Benadryl) will obviate this problem.
- Superficial thrombophlebitis. Injection of sclerosant creates a chemical thrombophlebitis that is controlled and affects only the treated area. However, at times the solution can travel proximally or distally and create an area of thrombus within the veins. The area overlying this often becomes red and tender. In most cases careful technique using only a small amount of solution (0.5 to 1 mL) will prevent this outcome. It is more likely to occur when injecting larger veins. When it does occur, the patient must be reassured that nothing serious has happened. Treatment

- consists of compression and an anti-inflammatory drug (e.g., ibuprofen).
- Thrombus formation. Clots can form in small veins or especially in the larger ones. They can be aspirated with a needle or incised and drained. Usually for the larger ones, a small amount of lidocaine is injected, then a no. 11 blade used to open the skin over the area. Pressure will expel the clot. No suture is needed. Thrombi are more common when larger veins are injected and if compression is not optimal postinjection. If a clot has been present for more than 4 weeks, it often organizes and then is difficult to remove.
- Postinjection itching and pain. Patients often complain of a transient itching after injection; some phlebologists apply steroid cream immediately after injection, but this is not necessary. The site of injections may become painful. Over-the-counter pain medication, including nonsteroidal anti-inflammatory drugs (NSAIDs), is adequate to control this and does not interfere with the effectiveness of treatment. Pain during the injection is minimal and well tolerated.
- DVT and pulmonary emboli. Fortunately, this is a rare complication. It is most likely to occur if too much solution is used and it gets into the deep system. Patients who have had a prior venous thromboembolic event or who have an underlying thrombophilia are more likely to have this problem. Birth control pills and estrogen may slightly increase the tendency toward this complication, but it is rare and their use does not contraindicate sclerotherapy. DVT may be reduced or eliminated by having the patient walk for 20 to 30 minutes after injection of large veins to avoid pooling in the deep venous system.

# POSTPROCEDURE PATIENT EDUCATION

Patients are asked to walk immediately after a session of sclerotherapy. Some therapists recommend 30 minutes, but even 5 or 10 minutes seems to be enough. Walking diffuses the solution that may have gone into the deep system and, more important, increases circulating fibrinolysins. (See the sample patient education form online at www.expertconsult.com.)

The same area should not be injected again for 3 to 4 weeks (Fig. 92-12). The patient can return at weekly intervals for treatment of alternate sites until treatment is complete. Patients should be able to resume normal activities, including high-impact aerobics

<sup>&</sup>lt;sup>†</sup>Many use standard 18.7% for all these indications.

and jogging, 24 hours after injections for spider veins; however, some therapists would further restrict patients for 1 week. No good prospective studies indicate the effect of robust activity on sclerotherapy.

# **CONCLUSION**

Sclerotherapy, when practiced properly, is a highly effective means of treating small to medium-sized varicose veins and telangiectases. Many therapists treat even large varicosities in this manner. Laser and other forms of light therapy are not as efficient and effective in most instances. At best they are useful for treating veins 3 mm in diameter or smaller. Equipment and methods may improve the results of light therapy, but sclerotherapy remains the gold standard for treating such veins. Careful work-up and management of patients with special attention to proper technique should provide good to excellent results in more than 90% of patients.

# **CPT/BILLING CODES**

Injections for telangiectasia, even if symptomatic, are rarely covered by insurance. Coverage for varicosities is quite variable. It is often necessary to document that conservative therapy (e.g., use of compression stockings) has failed. Frequently, preapproval and photographs will be required.

Most sclerotherapists do not deal with insurance companies and ask the patient to pay at the time of service. Some will charge by the number of injections and others by the amount of solution used; still others will inject for a certain time period (15 to 30 minutes). There are no routine standards.

# EXERCISE ELECTROCARDIOGRAPHY (STRESS) TESTING

Grant C. Fowler • Michael A. Altman

Seventeen million Americans have known coronary artery disease (CAD); however, in more than half of everyone else in whom CAD will be diagnosed, the diagnosis will *follow a bad outcome*—namely, a myocardial infarction (MI) or sudden cardiac death. Approximately one third of all deaths (more than half a million per year) in the United States are caused by CAD, the leading cause of death in both sexes. Exercise electrocardiography (ECG) testing (EET) is not only a safe (<1 event per 10,000 properly selected patients) and cost-effective method for diagnosing CAD, it is probably the most cost-effective method to screen for and manage CAD. EET can also be used to reassure patients about the safety of exercise and to customize their exercise prescription.

For the diagnosis of CAD, although much money, time, and effort have been spent designing and applying other tests with greater sensitivity, the sensitivity of EET exceeds 90% (perhaps 95%) for significant CAD—meaning left main CAD or multivessel disease with resultant left main equivalent CAD (i.e., left ventricular [LV] dysfunction resulting from ischemia). Supporting this, several studies have examined the incremental value of exercise myocardial perfusion imaging compared with EET for diagnosis and risk stratification of CAD. In an analysis of these studies, the modest incremental benefit of imaging did not appear to justify its cost (which has been estimated at \$20,550 per additional patient correctly classified). Consequently, the American College of Cardiology (ACC) and the American Heart Association (AHA) recommend a stepwise strategy for diagnosing CAD in patients with an intermediate pretest likelihood, using an EET as the initial test, and not an imaging procedure, if the patient is able to exercise, has a normal resting ECG, and is not taking digoxin\* (ACC/AHA/ASNC Guidelines). (See chapter 94, Stress Echocardiography, for testing patients with an abnormal resting ECG or who are taking digoxin, and for a dobutamine echo protocol for patients unable to exercise.)

With medical management of CAD more successful than ever, primary care clinicians' skills in managing CAD have become more important. Performing EET is one method of maximizing these skills. In fact, using the Duke Treadmill Score (DTS) or nomogram for positive tests, primary care clinicians can now risk-stratify and prognose CAD as well as their cardiologist colleagues. It should be noted that in the latest guidelines (2002, 2007) from AHA/ACC for management of stable CAD, an EET is a reasonable test for risk stratification in patients with a normal resting ECG and who are able to exercise. In part, these guidelines are based on "the simplicity, lower cost, and widespread familiarity with the performance and interpretation of the standard EET." Also, when patients divided into risk groups using EET have been studied with imaging (Gibbons and colleagues, 1999), few patients (<5%) who have a low-risk DTS (≤1% annual cardiac mortality rate) will be identified as high risk after imaging, and thus the cost of identifying these patients again argues against routine imaging. Those patients identified as high risk (≥3% per year annual cardiac mortality) should probably be referred directly for cardiac catheterization and a possible intervention (again, see Chapter 94, Stress Echocardiography). Only those patients with an intermediate DTS (>1% and <3%) seem to benefit from an imaging study to further differentiate low-risk patients from those who might benefit from an intervention.

Performing a maximal EET provides additional information valuable for predicting prognosis, such as exercise capacity and heart rate in recovery (HRR, explained later), even if the ECG cannot be used for interpretation or predicting prognosis. From a study of 7163 patients (Diaz and colleagues, 2001) with known or suspected CAD undergoing myocardial perfusion imaging at the Cleveland Clinic and for whom a DTS could not be calculated (e.g., patient taking digoxin, resting ECG abnormalities), the independent prognostic values of exercise capacity and HRR were determined. Patients were followed for an average of 6.7 years, and, when compared with results of myocardial perfusion imaging, not only did exercise capacity and HRR provide additional prognostic information, but if exercise capacity and HRR were both abnormal, it portended a higher risk of mortality than the result from the myocardial perfusion test in nonrevascularized patients.

Primary care clinicians can also use EET to screen certain asymptomatic individuals. Such screening may be especially helpful for diabetic patients, firefighters, anyone about to undergo noncardiac surgery, high-risk patients after revascularization, patients about to undergo cardiac rehabilitation, and older individuals about to embark on a vigorous exercise program. Although the ACC/AHA are not currently recommending EET to screen all asymptomatic individuals, there is emerging evidence that this will be a future growth area for the procedure. A negative EET demonstrating good exercise capacity combined with a negative multidetector (>32slice) computed tomography (CT) angiogram, which has a false negative rate of less than 2% for CAD, will likely be our ultimate screening test for CAD. In the meantime, with estimates that 12% of deaths in the United States are due to a lack of exercise, any method to motivate patients to exercise should be beneficial. EET can be used not only to reassure individuals of the safety of exercise, but to customize their exercise prescription. After almost every EET, patients should receive some type of customized exercise prescription based on their true maximal heart rate (MHR), their exercise (aerobic) capacity, and the test results. We now know that almost every patient benefits from an exercise program, even cardiac transplant recipients. In fact, of all the options available, exercise may be the single best method for improving endothelial function.

Benefits of performing EET in the primary care clinician's office include having test results immediately available, improving communication and referral patterns to cardiologists, and improving primary care clinicians' ECG reading skills. Clinicians performing EET also naturally improve their understanding of CAD pathophysiology as well as exercise physiology. With results immediately

<sup>\*</sup>EET has a higher specificity in the absence of 1 mm ST segment depression due to resting ST segment changes, LV hypertrophy, and digoxin use.

available, patient satisfaction is usually improved and liability from failure to diagnose should be decreased. Using the DTS when there is a positive study, the patient can immediately be counseled from an outcomes or prognosis perspective. Such data allow a patient to make a truly informed decision before undergoing a major procedure, such as coronary artery bypass graft (CABG) surgery. With personalized data, the patient can weigh his or her known risks of forgoing surgery against available known risks of an intervention, with interventions reserved for those who choose to accept the risks.

For primary care clinicians covering emergency departments or urgent care centers, or those working as hospitalists, knowledge of a patient's recent EET results may be helpful for perioperative evaluation. Management of patients with an acute chest pain syndrome is also greatly facilitated when EET is available. For many patients, after myocardial damage has been excluded by serial blood tests, resolution of the symptoms, and stabilized ECG findings, an EET may be useful for triage or early discharge. National guidelines with algorithms are available, and they have been demonstrated to be both safe and useful.

#### PHYSIOLOGY OF EXERCISE ECG TESTING

Performing exercise increases total oxygen demand and consumption, with the amount of increase depending on the size of the muscles used. In other words, the larger the muscles, the more oxygen is consumed. Oxygen demand and consumption also increase as the intensity of exercise increases. In response to increased exercise and oxygen demand, the body increases ventilation, oxygenation, cardiac output, and oxygen extraction by tissues. Unless there is moderate to severe lung disease (e.g., chronic obstructive pulmonary disease) or a process severely limiting oxygen transport or extraction (e.g., severe anemia), cardiac output is usually the factor limiting an individual's maximal exercise capacity. In turn, the limiting factor for cardiac output in those with obstructive CAD is usually coronary blood flow. Maximal exercise capacity can therefore be limited by coronary blood flow. In fact, maximal exercise capacity is usually quantified by measuring or estimating an individual's maximal oxygen uptake (VO2 max). In other words, maximal exercise with large muscles can be used both to estimate Vo<sub>2</sub> max and to evaluate limitations in coronary blood flow.

Cardiac output is calculated by multiplying the stroke volume by the heart rate; therefore, increases in either the stroke volume or the heart rate will increase the cardiac output. Increasing the stroke volume is generally a more efficient method of increasing cardiac output (i.e., requires less oxygen). However, unless the patient is taking a beta blocker, the initial physiologic response to increased demand for cardiac output is usually an increase in heart rate. (In part, this is why beta blockers work for treating angina; they block the increase in heart rate when there is a need for increased cardiac output, thereby forcing an increase in stroke volume and keeping the increased myocardial oxygen demand to a minimum.) Therefore, as intensity of exercise increases, heart rate increases up to a maximum (MHR), usually when the patient has reached maximal voluntary effort or exertion.

In normal patients there is a linear relationship between *myocardial* oxygen demand and heart rate. In other words, the faster the heart rate, the more oxygen the heart requires. Because the heart rate continues to increase as exercise intensity increases, so does the myocardial oxygen demand. MHR can be crudely *estimated* based on age (i.e., 220 -age in years  $\cong$ MHR) or by using graphs; however, *true* MHR is best determined with a maximal EET. MHR is the heart rate noted when the patient is at maximal voluntary effort (voluntarily fatigued), and this number should be recorded and given to the patient at the completion of each EET when the clinician is customizing an exercise prescription.

There is also a linear relationship between myocardial oxygen demand and systolic blood pressure (SBP). In other words, the higher the SBP, the harder the heart is working (and consequently the higher the myocardial oxygen demand). Therefore, one method

of quantifying the overall *myocardial* oxygen demand is to multiply the SBP by the heart rate; the product obtained is the *double product*, also known as the *rate-pressure product* (*RPP*). At any given moment the RPP is therefore an estimate of total myocardial oxygen demand; as long as the demand has not exceeded the supply, it is also a measure of total myocardial oxygen uptake or consumption. In other words, the higher the RPP, the more oxygen the heart is demanding; if supply is matching demand, the higher the capacity the heart has to deliver its own oxygen.

When the myocardium demands more oxygen, there are two options for supplying it: either the coronary arterial *flow* increases or the *extraction* of oxygen from the flow increases. As it turns out, increased myocardial oxygen demand during exercise is met primarily through an increase in coronary arterial flow rather than through increased oxygen extraction. This is because myocardial tissue is very efficient at extracting almost all of the available oxygen from the coronary arterial flow, even in the resting state. Therefore, coronary arterial *flow* is usually the limiting factor for cardiac oxygenation. This is especially true in patients with obstructive CAD.

With gradually increasing levels of exertion in the patient with obstructive CAD, a threshold is eventually reached where the heart's supply of oxygen cannot meet the demand. At this threshold, the heart becomes ischemic, initially at the subendocardial layer. With subendocardial ischemia, the patient usually demonstrates ECG changes in the form of ST segment depression. Usually, and eventually, this is followed by chest discomfort (i.e., angina). Because in most cases the ischemia is due to a fixed lesion, patients develop these ECG changes at about the same threshold or RPP every time. If symptoms occur, they also occur at the same RPP and follow the same pattern every time. In other words, angina caused by a fixed lesion does not radiate only into the left arm one day and into the right arm another day. If ST segment depression occurs (due to ischemia) and angina is not experienced, the diagnosis is silent ischemia

Large muscles, such as leg muscles, rapidly increase the oxygen demand with increased exertion (e.g., using a treadmill or bicycle). Vo<sub>2</sub> max is the greatest amount (i.e., volume) of oxygen that a person can extract from inspired air while performing dynamic exercise. It is usually reached when the patient is in the anaerobic range. Measuring Vo<sub>2</sub> max is a method of quantifying maximal exercise capacity, and  $\dot{V}_{O_2}$  max varies with body weight, heredity, sex, and exercise habits. It often decreases progressively with age, but this decrease may be purely due to inadequate exercise habits. Performing aerobic exercise on a regular basis may maintain a constant Vo<sub>2</sub> max for life. There is a nearly linear relationship between Vo<sub>2</sub> max and the maximum cardiac output; therefore the Vo<sub>2</sub> max is a measure of the functional capacity of the cardiovascular system. It can be measured directly with inspired/expired gas analysis or more easily estimated from a maximal EET. As mentioned previously, in those with CAD, Vo<sub>2</sub> max may be limited by coronary blood flow. With prognosis data discussed later in this chapter, estimating Vo<sub>2</sub> max is very important for predicting outcomes from a cardiovascular perspective.

Basal oxygen consumption, or 1 metabolic equivalent (1 MET), defines the amount of oxygen an average individual consumes sitting at rest, which is approximately 3.5 mL/kg/min (i.e., 1 MET = 3.5 mL/kg/min  $O_2$ ).  $VO_2$  max is often quantified as a multiple of the basal oxygen consumption in METs. For instance, walking 2 miles per hour (mph) on level ground requires approximately 2 METs. Walking 4 mph on level ground requires approximately 4 METs. Moderately active young men usually have a Vo<sub>2</sub> max of at least 42 mL/kg/min, or 12 METs. This means they are able to consume 12 times the amount of oxygen that they consume at rest. Obviously METs can also be used as a conversion factor between types of exercise. Charts are available (Fig. 93-1) to estimate a patient's exercise capacity or maximal METs by cross-referencing MET levels with different daily activities. This estimate may then be used to predict performance before placing a patient on a treadmill. Performing a maximal EET remains one of the more accurate methods

# VETERANS' ADMINISTRATION SPECIFIC ACTIVITY QUESTIONNAIRE

Instructions to patient: Draw a line below the activities done routinely with minimal or no symptoms, such as shortness of breath, chest discomfort, and fatigue.

1 MET: 2 METs:	Eating, getting dressed, working at desk Taking a shower
3 METs:	Walking slowly on a flat surface for one or two blocks
	Doing a moderate amount of work around the house, such as vacuuming, sweeping the floors, or carrying groceries
4 METs:	Doing light yard work (e.g., raking leaves, weeding, light carpentry, or painting)
5 METs:	Walking briskly (5 mph), dancing
6 METs:	Playing nine holes of golf carrying own clubs,
	performing heavy carpentry or mowing lawn with a push mower
7 METs:	Playing tennis (singles), carrying 60 lbs
8 METs:	Moving heavy furniture
	Jogging slowly, climbing stairs quickly, carrying 20 lbs upstairs
9 METs:	Bicycling at a moderate pace, sawing wood, jumping rope (slowly)
10 METs:	Swimming briskly, bicycling up a hill, walking briskly uphill, jogging 6 mph
11 METs	Skiing cross-country
	Playing basketball (full court)
12 METs:	Running briskly and continuously (level ground,
	8-minute miles)
13 METs:	Rowing, backpacking, any competitive activity, including those that involve intermittent sprinting, running competitively

Figure 93-1 Veterans' Administration specific activity questionnaire.

of estimating maximal METs. An individual's maximal METs, whether determined on a bicycle or a treadmill, has significant management and prognosis implications if the person has CAD. Even if the test is positive for CAD, achieving certain MET thresholds can be very reassuring for prognosis.

During a maximal EET, a perceived exertion scale (PES) may be helpful for monitoring the patient. The PES is similar to a pain scale; however, the patient quantifies "effort" or "exertion" instead of "pain" during testing. Originally studied and published with a scale from 5 to 20 (with 20 being the subjective maximum that an individual could work and 5 being minimal or no work at all), it has now been modified. Most clinicians in the United States use a range from 1 to 10 (Box 93-1) for the PES. Although it is a subjective measurement, in most patients the PES level is very reproducible; in other words, if they were asked to repeat the EET in 2 weeks, they would report the same PES level at the same workload and

Box	93-1. Perceived Exertion Scale
0	Nothing at all
0.5	Very, very weak
1	Very weak
2	Weak
3	Moderate
4 5	Somewhat strong
5	Strong
6	
7	Very strong
8	
9	
10	Very, very strong

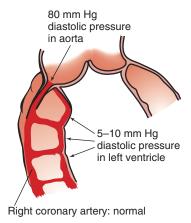

duration for both EETs. Interestingly, their heart rate is also usually very similar at a given PES. As a result, a PES target can be given to most patients to use as part of their exercise prescription. This replaces the patient's need to check the heart rate during exercise, and anything that simplifies an exercise prescription will, it is hoped, increase the chance of adherence/compliance.

A positive test result occurs when subendocardial ischemia causes ST segment depression on the ECG tracing. Because this is a "global" phenomenon, meaning much of the subendocardial layer is affected, it is almost always seen in more than one lead; if suspected it should be confirmed in an area of the ECG tracing where the baseline is relatively flat. True ischemia will cause ST segment depression for at least three beats in a row, and the ischemia (ST changes) usually persists or worsens during the recovery period. ST segment depression occurs because ischemia impairs the sodium/ potassium adenosine triphosphatase (Na<sup>+</sup>/K<sup>+</sup> ATPase) pump at the cellular level. Such an ST segment change can also be noted in patients taking digitalis, whose site of action is the Na<sup>+</sup>/K<sup>+</sup> ATPase pump. When the pump is affected, there is a resultant change in the Na<sup>+</sup>/K<sup>+</sup> intracellular gradient and a subsequent small shift in polarity. This shift in polarity is what is noted on the ECG tracing as ST segment depression.

With exercise-induced ischemia, ST segment depression becomes a global phenomenon, meaning it involves the entire subendocardium. When one area of the subendocardium becomes ischemic, there is a "fail-safe" mechanism that responds, meaning this subendocardial segment reduces its workload or shuts down before becoming permanently damaged. As a result, the remaining and surrounding subendocardium must work harder to compensate. This surrounding area subsequently becomes ischemic, and a domino effect occurs, cascading around the entire subendocardium. Consequently, ST segment depression is usually seen in multiple leads. In fact, this is such a global phenomenon that the coronary vessels involved cannot be predicted by which of the leads are demonstrating ST segment depression. (If knowledge of the coronary vessels involved or the total burden of ischemia is needed, an imaging test Imyocardial perfusion or echocardiogram, see Chapter 94, Stress Echocardiographyl should be added to the stress test.)

If the entire wall of the myocardium (full thickness) becomes ischemic, such as from severe CAD, ST segment elevation may be noted. It may appear very similar to that seen with a transmural/ST-elevation infarct or a ventricular aneurysm. In this situation, unless the clinician is certain that the finding is due to a ventricular aneurysm (e.g., associated with Q waves, or the clinician previously diagnosed/managed the infarct), the EET should be stopped. If either transmural ischemia or a new infarction is occurring, the potential for an arrhythmia is very high. However, transmural ischemia is rare in a community setting. In almost all positive EETs, ST segment depression is what is noted, the same as with what used to be called a subendocardial infarct. The subendocardial layer is usually the first to become ischemic because it is the "watershed" area of the heart, or the farthest from the arteries that are located in the epicardium (Figs. 93-2 and 93-3).

Certain other conditions may also make it difficult to perfuse the subendocardial layer, even in the absence of CAD. Normally the subendocardial layer is perfused during diastole and relies on perfusing "downhill" from 80 to 90 mm Hg of diastolic blood pressure (DBP) to an area where there is only 5 to 10 mm Hg pressure (i.e., end-diastolic pressure [EDP]). Thus, the pressure gradient, or the difference between "uphill" DBP and "downhill" EDP, is 80 or 90 minus 5 or 10, which is a 75 to 85 mm Hg difference (DBP - EDP = 75 to 85). If hypertension is poorly controlled, EDP may be elevated, reaching as high as 30 to 40 mm Hg, with the resultant drop in this pressure gradient (DBP - EDP = 40 to 60). In other words, there is much less "pressure" for blood to flow "downhill." Anything causing diastolic dysfunction, such as profound hypothyroidism or severe valvular disease, can also result in an elevated EDP, a decreased pressure gradient, and a false-positive EET result. A thickened myocardial wall, as seen in left ventricular hypertrophy, can

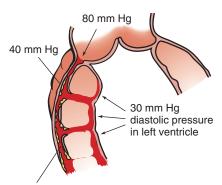

**Figure 93-2** Normal myocardial perfusion. Note perfusion gradient is from 80 mm Hg to 5 to 10 mm Hg. (Redrawn from Ellestad MH: Stress Testing: Principles and Practice, 4th ed. Philadelphia, FA Davis, 1996.)

make it physically difficult to perfuse through the wall, thereby causing subendocardial ischemia and ST segment depression, even without CAD. In addition to physical causes, other situations that can cause false-positive results include hypokalemia and other electrolyte imbalances. Inadequate potassium prevents the Na $^+/K^+$  ATPase pump from functioning correctly, resulting in ST segment changes. As mentioned previously, digitalis may also result in ST segment depression, even at physiologic doses.

# Normal Clinical Responses to Exercise ECG Testing

- 1. A gradual increase in heart rate to MHR where MHR is estimated by the formula 220 age (i.e., 220 age ≅ MHR). If a heart rate of 120 beats per minute (bpm) cannot be achieved, the diagnosis of *chronotropic incompetence* is possible (see "Interpretation" section).
- 2. Return of the heart rate to resting values within the first few minutes after exercise. The rate of return of the heart rate to its resting value depends partly on the exercise conditioning effect on vagal tone (i.e., frequent exercise or "being fit" increases vagal tone). An *abnormal* HRR is declared when the heart rate does not decrease by at least 12 bpm in the first minute of recovery (see "Interpretation" section).
- 3. A gradual rise in SBP. SBP is usually the highest at maximal workload. A drop in SBP during the exercise phase of EET, especially if it drops below resting standing SBP, may indicate severe CAD. An SBP greater than 214 mm Hg is designated a

Right coronary artery: CAD

**Figure 93-3** Myocardial perfusion in coronary artery disease (CAD). Note perfusion gradient is only from 40 mm Hg to 30 mm Hg. (Redrawn from Ellestad MH: Stress Testing: Principles and Practice, 4th ed. Philadelphia, FA Davis, 1996.)

- systolic hypertensive response to exercise (see "Interpretation" section).
- 4. A return of SBP and DPB to resting values by approximately 3 minutes after exercise. Failure of return of either blood pressure to normal by 3 minutes of recovery is also a *hypertensive response* to exercise (see "Interpretation" section).
- 5. Minimal change or a decrease in DBP during exercise. During exercise, the legs produce lactic acid, one of the most potent vaso-dilators known. As a result, a significant amount of blood volume flows into the legs. Because of this vasodilation, and the effects of exercise on Korotkoff sounds, diastolic pressure by auscultation can decrease all the way to zero in normal individuals. An increase in DBP of more than 10 mm Hg is also designated a diastolic hypertensive response to exercise (see "Interpretation" section).
- 6. Most patients perceive an increase by 1 to 3 points on the PES per stage of exercise. Few ever admit to reaching a full 10 points on the scale. For many patients, PES level increases rapidly from 7 to 9 when they are near maximal effort.

#### **INDICATIONS**

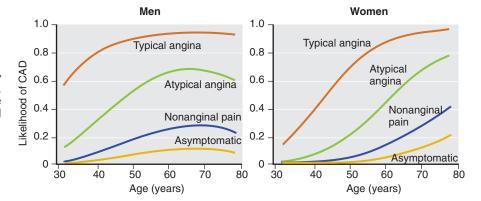

Comprehensive, national guidelines are available regarding the appropriate use of EET, including special cases and situations (e.g., diabetic patients, patients in the emergency department, firefighters, before noncardiac surgery, before and after revascularization). There are three general indications for EET: diagnosing CAD (especially helpful when evaluating atypical chest pain and screening asymptomatic patients at significant risk), managing CAD, and providing data for an exercise prescription while determining exercise capacity and safety. In certain cases, several of these indications are evaluated during the same procedure. An example would be a patient who has an intermediate pretest likelihood and is found to have CAD when performing the EET. Because the diagnosis has now been made, if it is considered safe to continue the procedure, prognosis may also be determined. Exercise capacity (i.e., aerobic capacity) could be determined if the patient were allowed to complete a maximal EET; this is helpful for determining prognosis. Based on the results, an exercise prescription along with cardiac rehabilitation might be initiated. In this manner, the diagnosis, management (e.g., prognosis, cardiac rehabilitation), and exercise prescription could all be determined during the same test.

### **General Indications**

- 1. Diagnosing CAD
  - Patients with an intermediate (20% to 70%) pretest probability of CAD based on sex, age, and symptoms (see "Determination of Pretest Likelihood," later; Fig. 93-4 and Table 93-1).
  - Asymptomatic patients with multiple risk factors, possible myocardial ischemia on ambulatory ECG monitoring, or an abnormal coronary calcium score from electron-beam computed tomography (EBCT) scan. It should be noted that asymptomatic patients are included in the graphs and tables (see Fig. 93-4 and Table 93-1) used to determine pretest probability.

**NOTE:** For diagnosing CAD, determining pretest likelihood is important. This is explained for patients with symptoms by examples in the section "Determination of Pretest Likelihood."

- 2. Managing CAD\*
  - Patients with known or highly probable CAD, for initial assessment or for a change in symptoms
  - After MI or revascularization (especially those at high risk), for prognostic assessment, activity prescription, evaluation of medical therapy, or cardiac rehabilitation
  - Demonstrating proof of ischemia before revascularization
  - Consider for perioperative evaluation of patients with CAD only if results would change management

**Figure 93-4** Pretest likelihood of coronary artery disease (CAD). (Redrawn from Diamond GA, Forrester JS: Analysis of probability as an aid in the clinical diagnosis of coronary-artery disease. N Engl J Med 300:1350–1358, 1979.)

Adapted from Diamond GA, Forrester JS: Analysis of probability as an aid in the clinical diagnosis of coronary artery disease. N Engl J Med 300:1350–1358, 1979. In Fowler GC, Evans CH, Altman MA: Office procedures: Exercise testing. Prim Care 24:375–406, 1997.

- Determining exercise prescription data, exercise capacity, and safety
  - Evaluation of exercise-related symptoms, including possible exercise-induced arrhythmias\* (also see Chapter 87, Ambulatory Electrocardiography: Holter and Event Monitoring).
  - Graded treadmill EET is one of the best methods for determining an individual's MHR. The exception is the elite athlete, for whom a sport-specific EET should be used.
  - True MHR must be known to calculate a training heart rate range, which can be used as a guideline for aerobic training.
  - An EET can also be used to estimate an individual's Vo<sub>2</sub> max, which is helpful in determining the current level of fitness or conditioning.

# **Specific ACC/AHA Indications**

For the sake of completeness of this chapter, most of the indications for EET in adults from the ACC/AHA guidelines will be listed. Guidelines for special cases (e.g., children, EET with expired ventilatory gas analysis) may be found in the ACC/AHA reference or on the AHA website (www.americanheart.org), under "Science and Professional, Scientific Publications, Scientific Statements." The

ACC/AHA guidelines use the following classification system for indications:

Class I: Conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective.
Class II: Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a procedure or treatment.

Class IIa: Weight of evidence/opinion is in favor of usefulness/efficacy.

Class Îlb: Usefulness/efficacy is less well established by evidence/opinion.

Class III: Conditions for which there is evidence and/or general agreement that the procedure or treatment is not useful/effective and in some cases may be harmful.

#### Exercise ECG Testing in Diagnosis of Obstructive CAD

Class I: Adult patients (including those with complete right bundle branch block [RBBB] or less than 1 mm of resting ST segment depression) with an intermediate pretest probability of CAD based on sex, age, and symptoms (see "Determination of Pretest Likelihood," Fig. 93-4, and Table 93-1).

Class IIa: Patients with vasospastic angina.

Class IIb: Patients with a high or low pretest probability of CAD by age, symptoms, and sex; patients with less than 1 mm of baseline ST segment depression and taking digoxin; patients with ECG criteria for LV hypertrophy (LVH) and less than 1 mm of baseline ST segment depression.

Class III: Patients with the following baseline ECG abnormalities: preexcitation syndrome (i.e., Wolff-Parkinson-White [WPW] syndrome), electronically paced ventricular rhythm, greater than 1 mm of resting ST segment depression, complete left bundle branch block (LBBB); patients with a documented MI or prior coronary angiography demonstrating significant disease and who have an established diagnosis of CAD. (Note that for diagnostic purposes, EET may not be useful. However, overall risk for individuals can be determined from obtaining Vo<sub>2</sub> max if it is deemed safe to test [see following sections "Risk Assessment and Prognosis in Patients with Symptoms or a History of CAD," "Exercise ECG Testing after Myocardial Infarction," and "Exercise ECG Testing before and after Revascularization"].)

# Risk Assessment and Prognosis in Patients with Symptoms or a History of CAD

Class I: Patients undergoing initial evaluation with suspected or known CAD. Patients with suspected or known CAD previously evaluated but now with a significant change in clinical status (specific exceptions noted in Class IIb). Low-risk patients with unstable angina (moderate or high likelihood of CAD with new-onset or progressive angina with walking) 8 to 12 hours after presentation or intermediate-risk unstable angina (prolonged [>20 minutes] or at rest angina; patients with prior MI, CABG,

<sup>\*</sup>Patients with LV dysfunction, history of recent (within 7 to 10 days) acute coronary syndrome, severe valvular (aortic) stenosis, or complex or life-threatening arrhythmias are considered a higher-risk group. Exercise testing for them should be performed in the hospital by a clinician with significant experience treating patients with CAD or with consultation by a cardiologist.

atherosclerotic cerebrovascular disease [ASCVD], or peripheral artery disease; aspirin use; age older than 70 years; or troponins negative or slightly elevated [<0.1 mg/mL]) 2 to 3 days after presentation; both groups of patients with unstable angina should have been free of active ischemic or heart failure symptoms.

Class IIa: Intermediate-risk patients with unstable angina who have initial cardiac markers that are normal, a repeat ECG without significant change, cardiac markers 6 to 12 hours after the onset of symptoms that are normal, and no evidence of ischemia during observation.

Class IIb: Patients with the following resting ECG abnormalities: preexcitation (i.e., WPW syndrome), electronically paced ventricular rhythm, greater than 1 mm of resting ST segment depression, complete LBBB. Patients with a stable clinical course who undergo periodic monitoring to guide treatment.

Class III: Patients with severe comorbidity likely to limit life expectancy or candidacy for revascularization. Patients with high-risk unstable angina (prolonged, ongoing >20 minutes pain at rest; pulmonary edema; new or worsening mitral regurgitant murmur; new/worsening rales; hypotension; bradycardia; tachycardia; age older than 75 years; transient ST segment changes; or elevated troponin [>0.1 mg/mL]).

#### Exercise ECG Testing after Myocardial Infarction

Class I: Before discharge for prognostic assessment, activity prescription, or evaluation of medical therapy (submaximal at about 4 to 7 days). Early after discharge for prognostic assessment, activity prescription, evaluation of medical therapy, and cardiac rehabilitation if the predischarge EET was not done (do a symptom-limited EET at about 14 to 21 days). Late after discharge for prognostic assessment, activity prescription, evaluation of medical therapy, and cardiac rehabilitation if the early EET was submaximal (do a symptom-limited EET at about 3 to 6 weeks).

Class IIa: After discharge for activity counseling or exercise training as part of cardiac rehabilitation in patients who have undergone coronary revascularization.

Class IIb: Patients with preexcitation syndrome (i.e., WPW syndrome), electronically paced ventricular rhythm, greater than 1 mm of resting ST segment depression, complete LBBB, digoxin therapy, LVH. Periodic monitoring in patients who continue to participate in exercise training or cardiac rehabilitation.

Class III: Patients with severe comorbidity likely to limit life expectancy or candidacy for revascularization. At any time after MI if there is uncompensated congestive heart failure (CHF), cardiac arrhythmia, or noncardiac conditions that limit the patient's ability to exercise.

# Exercise ECG Testing in Asymptomatic Patients without Known CAD

Class I: None.

Class IIa: Evaluation of asymptomatic persons with diabetes mellitus who plan to start vigorous exercise.

Class IIb: Evaluation of patients with multiple risk factors as a guide to risk reduction therapy. Evaluation of asymptomatic men older than 45 years of age and women older than 55 years of age planning to start vigorous exercise (especially if physically inactive), or involved in occupations in which impairment might affect public safety, or at high risk for CAD because of other diseases (e.g., peripheral vascular disease, chronic renal failure).

Class III: Routine screening of asymptomatic men or women.

**NOTE:** The class IIb indication evokes controversy because of the increased risk of false-positive results. However, with good clinical judgment or consultation of a table (e.g., Fig. 93-4, Table 93-1), the clinician may determine that the patient has a pretest likelihood as high as 15% to 20%, making the patient a reasonable candidate for EET.

#### Exercise ECG Testing for Valvular Heart Disease

Class I: In chronic aortic regurgitation, assessment of functional capacity and symptomatic responses in patients with a history of equivocal symptoms.

Class IIa: In chronic aortic regurgitation, evaluation of symptoms and functional capacity before participation in athletic activities. For prognostic assessment before aortic valve replacement in asymptomatic or minimally symptomatic patients with LV dysfunction.

Class IIb: Evaluation of exercise capacity in patients with valvular heart disease.

Class III: Diagnosis of CAD in patients with moderate to severe valvular disease or with baseline ECG abnormalities (preexcitation, electronically paced ventricular rhythm, >1 mm ST segment depression, complete LBBB).

#### Exercise ECG Testing before and after Revascularization

Class I: Demonstration of proof of ischemia before revascularization. Evaluation of patients with recurrent symptoms suggesting ischemia after revascularization.

Class IIa: After discharge for activity counseling or exercise training as part of cardiac rehabilitation in patients who have undergone coronary revascularization.

Class Ilb: Detection of restenosis in selected, high-risk (multivessel CAD, proximal left anterior descending CAD, family history of sudden cardiac death, diabetes, hazardous occupations, suboptimal results from the revascularization, saphenous vein graft,\* CHF\*) asymptomatic patients within the first 12 months after percutaneous coronary intervention (PCI). Periodic monitoring of selected, high-risk asymptomatic patients for restenosis, graft occlusion, or disease progression.

Class III: Localization of ischemia for determining site of intervention. Routine, periodic monitoring of asymptomatic patients after PCI or coronary artery bypass grafting without specific indications.

# Exercise ECG Testing for Investigation of Heart Rhythm Disorders

Class I: Identification of appropriate settings in patients with rateadaptive pacemakers.

Class IIa: Evaluation of patients with known or suspected exerciseinduced arrhythmias. Evaluation of medical, surgical, or ablative therapy in patients with exercise-induced arrhythmias (including atrial fibrillation).

Class IIb: Investigation of isolated ventricular ectopic beats in middle-aged patients without other evidence of CAD. Investigation of prolonged first-degree atrioventricular block or type I second-degree Wenckebach, LBBB, RBBB, or isolated ectopic beats in young patients considering participation in competitive sports.

Class III: Investigation of isolated ectopic beats in young patients.

#### Noninvasive Stress Testing before Noncardiac Surgery

Class IIa: Noninvasive stress testing of patients with three or more clinical risk factors (e..g, CAD, CHF, ASCVD, diabetes mellitus, renal insufficiency) and poor functional capacity (<4 METs or cannot walk up a flight of stairs) who require high-risk (often >5% risk of serious complications) surgery (e.g., vascular, defined as aortic or other major vascular, peripheral vascular surgery) is reasonable if it will change management.

Class IIb: Noninvasive stress testing may be considered for patients with at least one to two clinical risk factors and poor functional capacity (<4 METs) who require intermediate-risk (1% to 5% risk of serious complications) noncardiac surgery (e.g.,

<sup>\*</sup>Although not listed as high risk in ACC/AHA guidelines, patients with these conditions have worse long-term outcomes postrevascularization.

intraperitoneal; intrathoracic; carotid or aortic stent; carotid endarterectomy; head and neck, orthopedic, or prostate surgery) if it will change management. Noninvasive stress testing may be considered for patients with at least one to two clinical risk factors and good functional capacity (≥4 METs) who are undergoing high-risk/vascular surgery.

Class III: Noninvasive testing is not useful for patients with no clinical risk factors undergoing intermediate-risk or low-risk (<1% risk of serious complications) noncardiac surgery (e.g., endoscopic, superficial, cataract, breast, ambulatory).

#### **Indications for Diabetic Patients**

Because of a disproportionate burden of CAD in diabetic patients, the American Diabetes Association (ADA) has developed indications for cardiac testing in diabetic patients. They include the following:

- 1. Patients with typical or atypical cardiac symptoms
- Patients with an abnormal resting ECG, especially if suggestive of ischemia or infarction

The ADA has recognized additional risk factors for obstructive CAD in diabetic patients, including renal disease (40% risk of coronary event in 5 years), evidence of other atherosclerotic disease (90% of their deaths are due to CAD), cardiovascular autonomic neuropathy (e.g., tachycardia, bradycardia, orthostatic hypotension, inadequate heart rate acceleration with exertion), older age, and female sex.

# **Indications in the Emergency Department**

Patient has or had chest pain and fulfills the following requirements:

- 1. Two sets of negative cardiac markers from each of two different types of assays (troponin, myoglobin, or creatinine kinase MB) at 4-hour intervals.
- 2. Pre-exercise 12-lead ECG shows no significant changes compared with original ECG at the time of presentation to the emergency department.
- Absence of baseline (resting) ECG abnormalities that would preclude accurate assessment of the EET.
- 4. From admission to the time that results are available from the second set of cardiac markers, the patient has become asymptomatic, has had lessening of chest pain symptoms, or has had persistent atypical symptoms.
- 5. Absence of ischemic chest pain at the time of EET.

#### **Indications for Firefighters**

The following guidelines were recommended by the National Fire Protection Association (NFPA) in 2000:

- 1. At age 40 years, periodic treadmill testing should be performed. The frequency should increase with age, but at a minimum the test should be done every 2 years.
- 2. At age 35 years, periodic treadmill testing should be performed for individuals with one or more coronary risk factors (premature family history [younger than age 55 years], hypertension, diabetes mellitus, cigarette smoking, and hypercholesterolemia [total cholesterol >240 or high-density lipoprotein <35]).

#### **Indications before Noncardiac Surgery**

Half of serious complications related to noncardiac surgery are cardiovascular. Although older patients have the highest risk of a cardiovascular complication with surgery, they also make up the largest group of patients undergoing surgery. Consequently, as the population ages, the cardiovascular risk of surgery will increase.

Guidelines are available for screening patients before noncardiac surgery, and the ACC/AHA guidelines have been studied from an outcomes perspective. Box 93-2 provides some shortcuts for determining need for noninvasive testing. Patients about to undergo low-risk surgery (<1% risk; e.g., endoscopic, superficial, cataract, breast, ambulatory surgery) or with at least a fair functional/exercise capacity do not need further testing. If the patient has undergone revascularization (PCI or CABG) within the past 5 years or a thorough evaluation of the coronary arteries (e.g., EET, stress imaging) within the past 2 years, and there has not been a change in symptoms suggestive of ischemia, then according to ACC/AHA guidelines no further testing is necessary. Conversely, if high-risk (often >5% risk of serious complications) vascular surgery is planned and the patient has three or more clinical risk factors (i.e., CAD, CHF, ASCVD, diabetes, or renal insufficiency [creatinine  $\geq 2 \text{ mg/dL}$ ], noninvasive testing is reasonable if the results will change the management. It should be kept in mind that the goal of perioperative cardiac assessment is to detect the patient who would benefit from revascularization anyway, not just to get him or her through surgery. (See also Chapter 230, Preoperative Evaluation.)

Noninvasive testing is also probably indicated if the patient has poor functional/exercise capacity and one or more clinical risk factors. For intermediate-risk (1% to 5% risk of serious complications) surgery (e.g., intraperitoneal; intrathoracic; carotid or aortic stent; carotid endarterectomy; head and neck, orthopedic, or prostate surgery) or high-risk surgery with only one or two clinical predictors, there is insufficient evidence to determine the best

# Box 93-2. Shortcuts to Determine Indicators for Noninvasive Testing before Noncardiac Surgery

No testing necessary if "Yes" to any of these four questions:

- 1. Is this low-risk surgery (e.g., endoscopic, superficial, cataract, breast, ambulatory surgery)?
- 2. Does the patient have fair functional/exercise capacity (≥4 METs) and no symptoms?
- 3. Has the patient undergone revascularization (CABG or PCI) within past 5 years without a change in symptoms indicating ischemia?
- 4. Has the patient had a thorough cardiac evaluation within past 2 years without a change in symptoms indicating ischemia?

Conversely, if vascular surgery is planned and the patient has three or more clinical risk factors, noninvasive testing is reasonable if the results will change the management.

Also, if "Yes" to both the following questions, noninvasive testing is reasonable\*:

- Poor functional/exercise capacity by questionnaire or specific questioning (<4 METs, or inability to climb one flight of stairs)?
- 2. Clinical risk factor present (CAD, CHF, ASCVD, diabetes, or renal insufficiency)?

<sup>\*</sup>For intermediate- or high-risk surgery with only one or two clinical predictors present, there is insufficient evidence to determine the best management, beta blockade therapy versus noninvasive testing. From Fleisher LA, Beckman JA, Brown KA, et al: ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: Executive summary. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery). Circulation 116:1971–1996, 2007.

management, beta blockade therapy versus noninvasive testing. Also, high-risk surgery (e.g., aortic/major vascular surgery, peripheral vascular surgery) may be managed like intermediate-risk surgery if only one or two clinical risk factors are present.

# Indications before and after Revascularization (PCI or CABG)

In recent years, at least nine studies (BARI, CABRI, RITA-1, EAST, GABI, Toulouse, MASS, Lausanne, ERACI) have been published comparing PCI with CABG in patients with symptomatic CAD. Most were smaller studies, but BARI (the Bypass Angioplasty Revascularization Investigation) included 1829 patients, CABRI (Coronary Angioplasty vs. Bypass Revascularization Investigation) 1054 patients, and RITA-1 (first Randomized Intervention Treatment of Angina trial) 1011 patients. Although these trials differ slightly in their design and in the sort of patients who were included, the findings have all been remarkably consistent. At almost any point after initial treatment, whether the patient was treated with PCI or CABG, the rates of death or nonfatal MI are essentially the same. However, at the time of these trials, patients undergoing PCI usually received percutaneous transluminal coronary angioplasty (PTCA). Consequently, the reintervention rate was much higher among patients initially treated with PCI than for those undergoing CABG. There have been several additional trials (ERACI II, ARTS, SOS) using stents for PCI and comparing outcomes with CABG. Although the reintervention rate remains higher with PCI than CABG, it has been significantly reduced with the use of stents. Mortality and nonfatal MI rates have again remained basically the same whether the patient is treated with PCI or CABG. The BARI trial 10-year follow-up data are now published; overall, the annual mortality rate was 2.8%. Consequently, there are going to be many patients having undergone revascularization living a long time.

From the BARI trial, we also learned about EET postrevascularization. Per protocol, at years 1, 3, and 5, 1388, 1208, and 1097 patients, respectively, underwent EET (Krone and colleagues, 2001). Only 9% experienced angina when taking the EET, consistent with the "protocol- not symptom-driven" indication for EET. Overall, patients taking EET during the first 3 years of the study not only had a very low risk of mortality or MI, but very rarely did EET results affect management. The authors concluded that their study supported ACC/AHA guidelines, which do not recommend routine testing for 3 to 5 years after successful revascularization. The authors also speculated that exercise imaging would not have been helpful because such a low-risk population would have likely produced a large percentage of false-positive results. Consequently, only a fraction of those with a significant perfusion or echocardiographic defect would have had a subsequent event.

From the BARI trial, we also learned about risk stratification postrevascularization, including the risk of not undergoing EET according to protocol. In the asymptomatic population that did not follow the protocol, not taking the EET was a stronger predictor of mortality than results of the EET in those who followed the protocol. Overall, nonexercisers had a 3- to 10-fold increased risk of mortality compared with exercisers. Diabetic nonexercisers who had undergone CABG had a 30% 5-year mortality rate. Even more striking, diabetic nonexercisers who had undergone PTCA had a 52.4% 5-year mortality rate!

We have long known that patients with CAD and poor functional or exercise capacity (<4 METs) are at high risk for cardiovascular events, and that is one of the criteria for considering EET or other noninvasive testing when evaluating patients before surgery. Such a low exercise capacity may correlate with what the BARI investigators found to be nonexercisers. Regardless, clinicians should be aware that patients unable to exercise are at high risk postrevascularization.

How then should we monitor patients postrevascularization? Interestingly, of the nine studies comparing PCI with CABG, most

# Box 93-3. Criteria for High-Risk Patients Postrevascularization

Multivessel CAD
Proximal left anterior descending CAD
Family history of sudden cardiac death
Diabetes
Hazardous occupations
Suboptimal results from the revascularization

Saphenous vein graft\*

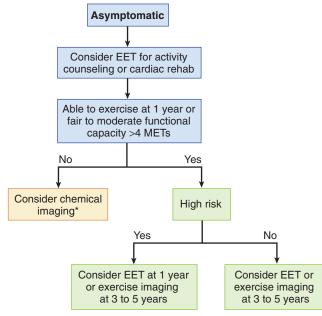

Congestive heart failure\*

\*Although not listed as high risk in ACC/AHA guidelines, patients with these conditions have worse long-term outcomes postrevascularization compared with other patients.

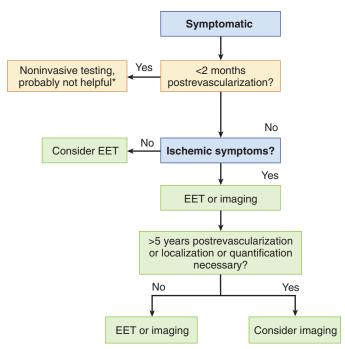

used EET at various points to monitor patients for safety. Although the ACC/AHA guidelines suggest that an exercise imaging test is the preferred method of evaluating patients postrevascularization, the experts designing these trials considered EET to be adequate. Regardless, ACC/AHA guidelines also list certain situations where EET may or may not be helpful in the revascularized patient.

A reasonable use for EET in the revascularized patient is after discharge for activity counseling or exercise training as part of a cardiac rehabilitation program (indication: class IIa). Although the evidence is less well established, EET may be considered for the detection of restenosis in the first months after PTCA in selected, high-risk (Box 93-3), asymptomatic patients (indication: class IIb). And although the evidence is likewise less well established, EET may be considered for periodic testing for restenosis, graft occlusion, or disease progression in selected, high-risk (see Box 93-3), asymptomatic individuals postrevascularization (indication: class IIb).

What about the patient who has remained asymptomatic, is more than 5 years postrevascularization, and needs to be evaluated before surgery? Figure 93-5 incorporates the ACC/AHA guidelines for these patients as well as most asymptomatic patients postrevascularization.

**Figure 93-5** Algorithm for exercise ECG testing (EET) in the asymptomatic patient postrevascularization. \*Especially those with prior MI and/or renal insufficiency.

**Figure 93-6** Algorithm for exercise ECG testing (EET) in the symptomatic patient postrevascularization. \*However, CT angiography may be helpful (≥16-slice post-CABG; ≥32-slice post-PCI).

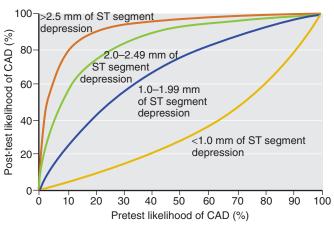

What tests should be used if the patient becomes symptomatic postrevascularization? Figure 93-6 provides an algorithm for these patients. As multislice CT angiography becomes more readily available, combining it with an EET may be the screening and diagnostic procedure of choice for revascularized patients.

### **Determination of Pretest Likelihood**

If the goal of the EET is to exclude CAD, determining pretest likelihood will help decide whether EET is the indicated and proper procedure. For diagnostic purposes, EET is most valuable for patients with an intermediate (20% to 70%) pretest likelihood. Simple graphs and tables are available that require only three variables to estimate pretest likelihood in symptomatic individuals (see Fig. 93-4 and Table 93-1). With a pretest likelihood in the 20% to 70% range, an abnormal or positive EET result provides strong justification for additional studies, including invasive studies. A negative EET may provide justification for merely close observation with frequent follow-up visits.

The value of using this range (20% to 70%) is further demonstrated with a graph of post-test likelihood of CAD (Fig. 93-7). From this graph, the clinician should be able to see that the most information is obtained from patients with an intermediate pretest likelihood. In other words, for Figure 93-7 the vertical gap is largest between what would be a positive EET and a negative EET for patients in the intermediate pretest range. In this group, positive studies are most clearly delineated from negative studies; therefore, the most information is obtained. For example, a patient with a pretest likelihood of 40% with 2 mm or more of ST segment depression now has more than an 85% post-test likelihood of CAD. Such a post-test likelihood would justify an invasive procedure. However, in the same patient, less than 1 mm of ST segment depression (a negative EET) lowers the risk of CAD to less than 20%. Close follow-up of this patient may be adequate.

For patients with a low (<20%) pretest likelihood, although there may be other benefits of performing EET (e.g., customized

**Figure 93-7** Post-test likelihood of coronary artery disease (CAD) with positive (>1 mm ST segment depression) and negative (<1 mm ST segment depression) test results. (Redrawn from Epstein SE: Implications of probability analysis on the strategy used for noninvasive detection of coronary artery disease: Role of single or combined use of exercise electrocardiographic testing, radionuclide cineangiography and myocardial perfusion imaging. Am J Cardiol 46:491–499, 1980.)

exercise prescription), positive studies are more likely to be bothersome false-positive results that lead to unnecessary patient anxiety and further expensive diagnostic testing. On the other hand, a negative test in the high pretest likelihood group (>70%) may not be sufficient to exclude CAD. For the young or very active individual with a high pretest likelihood, coronary angiography is diagnostic and might be a more appropriate study. Again, to use an example, a patient with a pretest likelihood of 90% who has a positive study (>2 mm ST segment depression) has approximately a 96% post-test likelihood (using Fig. 93-7). This is only a 6% gain in probability, which is very little information. If the EET is negative, the patient still has a 75% likelihood of CAD. For diagnostic purposes, this probability certainly does not rule out CAD, so EET has apparently been of little value. (Again, even in patients for whom little diagnostic information is gained with EET, performing it may be helpful for other reasons, such as for managing CAD.)

Pretest likelihood can be estimated by a description of the chest pain and the patient's sex and age. *Typical angina* is described (Diamond and Forrester, 1979) as substernal, exertional, and relieved by rest or nitroglycerin. Chest discomfort with two of these three characteristics is *atypical angina*; with only one it is *nonanginal chest pain*. Using these three descriptions, pretest likelihood tables and their corresponding graphs (see Fig. 93-4 and Table 93-1) can be readily applied to determine pretest likelihood.

Although Figure 93-4 and Table 93-1 also include asymptomatic patients, in general asymptomatic patients never reach an intermediate (20%) pretest likelihood. This is why mass screening of the asymptomatic population with EET is not recommended. It should be kept in mind that the data for Figure 93-4 and Table 93-1 were compiled from a community with an average number of risk factors (at the time, not many individuals had multiple risk factors). Therefore, for an individual patient with severe abnormalities in each of the risk categories, such as severe hypertension, heavy smoking, and severe hypercholesterolemia, or possessing multiple risk factors, pretest likelihood should be increased even if he or she is asymptomatic. Tables similar to Table 93-1 have been developed that attempt to adjust for severity of risk factors, but few experts use them because they have mostly been developed from patients seen in referral centers as opposed to the community. In the asymptomatic group, the Framingham calculator (available online at http://hp2010.nhlbihin.net/atpiii/calculator.asp) or tables (including international tables similar to those developed for the

Framingham Study) can also be used to help quantify risk. Although the Framingham calculator is designed to estimate absolute risk of a coronary event over the next 10 years, combining this result with clinical gestalt, clinicians can estimate which asymptomatic patients with risk factors would possibly reach the 20% pretest likelihood and benefit from EET. It should also be kept in mind that approximately one third of individuals who developed CAD in the Framingham Study had none of the usual risk factors, so generous estimates should be made when assessing pretest likelihood. As newer risk factors (e.g., chronic kidney disease; elevated homocysteine, ferritin, high-sensitivity C-reactive protein, fibrinogen, apolipoprotein [B], LDL particle number, or lipoprotein [A] levels) are studied, the clinician may again have to use clinical judgment or gestalt to correctly estimate pretest likelihood for an individual with these risk factors.

# **CONTRAINDICATIONS**

#### **Absolute**

- Very recent acute MI (within 2 days) or other acute cardiac event
- High-risk unstable angina
- Severe symptomatic LV dysfunction or uncontrolled symptomatic CHF
- Potentially life-threatening or uncontrolled cardiac arrhythmias causing symptoms or hemodynamic compromise
- · Acute pericarditis, myocarditis, or endocarditis
- Symptomatic severe aortic stenosis
- Acute aortic dissection
- Acute pulmonary edema, embolus, or infarction

#### Relative

- Left main coronary stenosis
- Moderate stenotic valvular heart disease
- Third-degree atrioventricular block or second-degree Mobitz type II block without pacemaker
- Tachyarrhythmias or bradyarrhythmias
- Severe arterial hypertension (resting >200 mm Hg systolic or >110 mm Hg diastolic)
- Hypertrophic cardiomyopathy or other form of outflow obstruction
- Acute thrombophlebitis, deep venous thrombosis, or intracardiac thrombi
- Electrolyte abnormality
- Acute or serious general illness or infection
- Neuromuscular, musculoskeletal, or arthritic condition that precludes exercise
- Uncontrolled metabolic disease, such as diabetes, thyrotoxicosis, or myxedema
- Medication intoxication from drugs such as digoxin, sedatives, or psychotropic agents
- Patient inability or lack of desire or motivation to perform the test, including severe emotional distress
- Unavailability of advanced cardiac life support (ACLS) equipment or of an individual certified to perform ACLS

**NOTE:** In selected cases, a skilled cardiologist may perform testing for patients with one of these diagnoses (generally in a referral center). All are contraindications to EET in the office.

### Contraindications in the Emergency Department

- New or evolving abnormalities on the resting ECG
- Abnormal cardiac markers
- Inability to perform exercise
- Worsening or persistent ischemic chest pain symptoms from admission to the time of EET
- Clinical risk profiling indicating coronary angiography is likely
- Any routine contraindications from the previous section

#### **Additional Relative Contraindications**

There are certain conditions that produce a study that is difficult to interpret or that will have results that add very little clinical information. Such relative contraindications include:

- Ventricular aneurysm
- Chronic infectious disease (e.g., mononucleosis, hepatitis, advanced human immunodeficiency virus infection)
- Fixed-rate pacemaker (rarely used)
- Advanced or complicated pregnancy
- Frequent or complex ventricular ectopy

#### **EQUIPMENT**

• A treadmill with adjustable speed and grade and adequate weight capacity: This is by far the most common equipment used for EET in the United States. Advantages include the ability to test most patients under the actual physiologic conditions of exercise. The most common types of exercise performed in the United States are walking and running. In addition, patient motivation wavers less during the treadmill test than with the bicycle EET. Disadvantages include the fact that the treadmill may be difficult to use for patients with lower extremity or low-back problems or for patients who are very obese. The equipment is also more expensive, causes more motion artifact, and is noisier than a bicycle ergometer.

**NOTE:** If a treadmill is chosen, it should have a warm-up speed of about 0.5 to 1.5 mph, with testing speeds ranging from 2.0 mph up to 12 mph. For elite athletes, the speed may need to reach 15 mph. The slope or grades possible should range from 0% (flat) to 20%. If testing elite athletes, the grade may need to reach 25%. It should also be able to accommodate the patient's weight; capacity for some models is now 500 pounds.

- Bicycle ergometers: Bicycle ergometers use adjustable resistance and pedal frequency to exert the patient (Fig. 93-8). Advantages with the bicycle ergometer include easier-to-obtain blood pressure (BP) measurements and the ability to terminate the test instantly. Many patients feel more secure sitting on the bicycle. Unfortunately, in the United States leg fatigue is common because most patients do not bike. In fact, as a result of leg fatigue the procedure often fails to determine Vo<sub>2</sub> max. Bicycle ergometry also depends on motivation throughout its duration. As a result, if the patient can tolerate the treadmill, most U.S. clinicians prefer it.
- Arm ergometer: The arm ergometer (Fig. 93-9) enables patients with severe orthopedic problems to be tested. However, muscle fatigue often occurs before the maximum heart rate is achieved.
- Continuous ECG monitor: A three- to six-lead model with a screen-freeze or capture/replay option is desirable (Fig. 93-10).
   Although previous models provided only 3 or 4 beats in each lead

Figure 93-8 Bicycle ergometer.

Figure 93-9 Arm ergometer.

if 6 or more leads were monitored, newer equipment often allows clear simultaneous monitoring of all 12 leads.

- 12-Lead ECG recorder: With modern equipment, the recorder also runs the treadmill. Recent developments for primary care offices (e.g., wider wheelbase) allow the recorder to be wheeled from room to room for routine ECGs. Interpretive packages for 12-lead ECGs are also convenient. Most equipment is now digital, allowing data to be filtered to provide a smooth baseline. However, it is important to avoid overfiltering the data and, in so doing, filtering out ST segment depression. Newer models are personal computer–based and can use either thermal paper or a laser printer. Many are compatible with electronic medical records.
- Sphygmomanometer, including various cuff sizes: A gauge manometer is adequate because the most important readings are those relative to resting pressures (not the absolute pressures).
- Stethoscope.
- Razor, rubbing alcohol, skin abrasive.
- Electrodes: Disposable electrodes designed for EET (regular ECG electrodes are not adequate and will cause artifact).
- Cables and belt: A disposable or washable belt is preferred because patients usually sweat.
- Emergency equipment (see Fig. 220-4 in Chapter 220, Anaphylaxis): Defibrillator; oxygen; airway, intubation, and suction equipment; and an emergency drug kit containing intravenous fluids, tubing, and medications to support ACLS protocols.

Figure 93-10 ECG monitor. (Courtesy of Cardiac Science/Burdick, Inc., Deerfield, Wisc.)

Figure 93-11 Trained technician monitoring patient.

NOTE: It is also helpful to have a trained technician (Fig. 93-11) to assist during the procedure. Technician certification for EET is available through the American College of Sports Medicine. In many centers the technician prepares the patient; monitors the ECG, the patient's response to exercise, the heart rate, and the BP; and prepares the results for interpretation. For low-risk patients, the technician may actually perform the entire study without a physician being present. Otherwise, the clinician should examine the patient before, during, and after the procedure, confirm which protocol to use, and terminate the study. The clinician should monitor the ECG tracing when the technician is taking BP readings, and the clinician should interpret the final results.

## **Written Procedure Protocols**

- Informed consent (see the sample consent form "Cardiac EET" in Appendix B)
- Medical history, physical examination, handwritten report form (Fig. 93-12)
- Criteria for stopping EET (see the section on "Test Termination Criteria," later)
- Emergency response plan (should be designed for every office and kept on file in event of a complication from EET)
- Quality assurance plan, including calibration and testing of equipment

**NOTE:** All emergency equipment should be checked daily and medications should be checked weekly to monthly, depending on their use. The EET equipment should be inspected and calibrated periodically, based on manufacturer recommendations. ACLS certification cards should be kept on file along with the information and protocols listed previously.

## PREPROCEDURE PATIENT PREPARATION

Deconditioned patients or those anticipated to have a poor exercise capacity (see the Veterans' Administration [VA] Specific Activity Questionnaire, Fig. 93-1):

• In the geriatric or physically inactive population, it is safe to exercise to a heart rate of 100 bpm, regardless of age, without prior testing. In those anticipated to have very poor exercise capacity, if they are not in urgent need of a cardiovascular intervention, it may be reasonable to help them increase their exercise capacity before undergoing an EET. This may be achieved with a walking program for several weeks or even months, four or five times a week, with a target heart rate of 100 bpm. In this manner

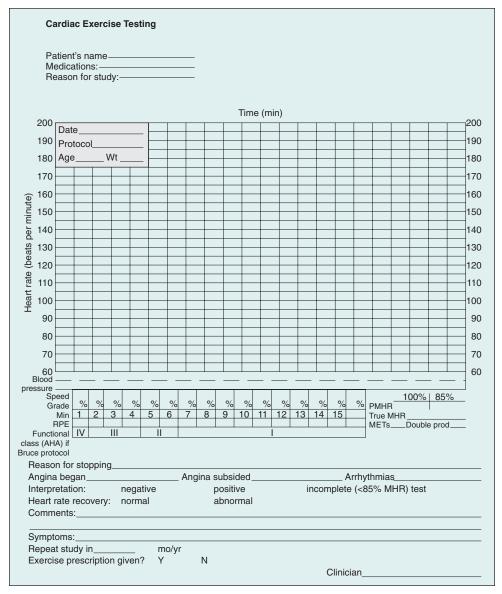

Figure 93-12 Exercise test results form. METs, metabolic equivalents; PMHR, predicted maximum heart rate (220 – age). (Modified from Evans CH, Karunaratne HB: Exercise stress testing for the family physician: Part I. Performing the test. Am Fam Physician 45:121–132, 1992.)

it may be possible to avoid some uninterpretable or incomplete tests.

Before arrival

- The patient should be instructed to minimize consumption of alcohol, over-the-counter medications, and caffeine, both the day before and the day of the procedure. The patient should be encouraged to get a good night's sleep the night before the procedure. Patients should not eat for 2 hours before the test. It might be advisable for the most recent meal to be a small and predominately liquid meal. To minimize the risk of patient fatigue, many clinicians prefer performing EET in the morning. They then instruct the patient to avoid breakfast or to have only a liquid breakfast that day.
- The procedure should be rescheduled, if possible, if the patient has a cold or other viral illness or is not feeling well in general.
- If the indication for the test is to diagnose CAD (as opposed to managing CAD) or to screen for CAD, the clinician should instruct the patient to avoid taking beta blockers (or rate-limiting calcium channel blockers) the day of the test.

**NOTE:** Digoxin can cause artifact even at therapeutic doses. If possible, digoxin should not be taken for 2 weeks before a test, the amount of time necessary for its elimination. However, a negative EET in a patient taking digitalis is a good study. Estrogen and tricyclic antidepressants can have similar effects and can be managed the same way. Beta blockers can suppress the heart rate and prevent determination of the MHR. Patients who discontinue beta blockers should watch closely for "rebound" symptoms and, if they develop, should restart their beta blockers. Because angiotensin-converting enzyme inhibitors or angiotensin receptor blockers have little or no effect on performance of an EET, frequently they may be used as a substitute antihypertensive. If necessary, they can be taken on the day of the test and usually work within an hour. Clonidine may be used in the same manner.

- If the indication for the test is to determine pharmacologic efficacy in patients with CAD, obviously beta blockers should be taken the day of the study.
- The clinician should instruct the patient to bring shoes and clothing that are comfortable for walking and possibly for

jogging. Bras with underwiring are contraindicated; sports bras work well.

 To minimize patient worry and stress (which often cause an elevated resting SBP), the clinician should explain that the risk of death for patients being tested using a treadmill is very small, and even less in an office setting (<1 per 10,000 patients).</li>

After arrival

- The clinician should again explain the reasons for the test and answer any questions.
- The procedure should be explained again to the patient (e.g., how frequently the workload will be increased, how BP measurements will be taken, how the PES works).
- The patient should be assured that close monitoring will take place and reassured that although the procedure exerts the heart, it is a relatively safe procedure (<1:10,000 mortality rate).
- The patient should know what symptoms to report during the test.
- The clinician should explain to the patient how to terminate the procedure should he or she have severe symptoms or an emergency.
- Signed, written informed consent should be obtained (see sample online at www.expertconsult.com).

#### **DETERMINING PROTOCOL**

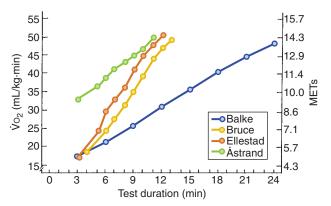

There are many excellent protocols available; the choice usually depends on the patient's predicted exercise capacity and clinician preference. The VA Specific Activity Questionnaire (see Fig. 93-1) may be very helpful for predicting exercise capacity and deciding between a regular protocol and a modified (less aggressive) protocol. If a patient can walk up a flight of stairs carrying a bag of groceries, he or she should be able to tolerate a regular Bruce or Balke protocol. Choose a protocol that starts at a low level of exertion (2 to 3 METs) and then gradually increases.

- A protocol with stage durations of at least 3 minutes (2 minutes for bicycle ergometer) allows more physiologic adaptation to the workload of each stage.
- 2. Workload increases that are no greater than 1 to 3 METs per stage also allow more physiologic adaptation.
- 3. Choose a protocol (Fig. 93-13) with a target of completing the EET in less than 15 minutes (even more preferable is 10 minutes or less). EETs that last more than 15 minutes may produce fatigue and overheating, which can independently affect results.

The Bruce protocol (Table 93-2) is the most frequently used protocol and has been the most extensively studied and validated. It is especially useful in active patients and takes less time than other protocols because it rapidly increases workload. Conveniently, the number of METs the patient will achieve is about the same as the number of minutes it takes to complete an EET using the Bruce protocol. A formula is available for estimating maximal exercise capacity in METs for the Bruce protocol. In men, this is METs =  $(2.94 \times [\text{min Bruce}] + 7.65)/3.5$ . For women, the formula is METs =  $(2.95 \times [\text{min Bruce}] + 3.74)/3.5$ .

The Bruce protocol also has its disadvantages; by the fourth or fifth stage, the patient will need to run, which increases artifact. In addition, the patient often experiences difficulty accommodating increases in both slope and speed at the same time. Elderly patients usually have decreased proprioception in their toes and some degree of impairment in both vision and balance, making it especially difficult for them to adjust to changes in slope and speed at the same time.

In general, most "modified" protocols, such as the modified Bruce or modified Balke protocols, have a reduced progression of workload and are better tolerated by debilitated patients. Modified protocols usually maintain the same speed and vary only the elevation.

**Figure 93-13** Oxygen uptake measured according to time of exercise on four different protocols. (From Pollock MI, Bohannon RL, Cooper KH, et al: A comparative analysis of four protocols for maximal treadmill stress testing. Am Heart | 92:39–46, 1976.)

Gradual but continuously increasing workload protocols (e.g., ramp) are also available. Table 93-3 indicates various protocols and Figure 93-13 graphically compares METs per minute and  $\dot{V}o_2$  max as measured for four protocols. If the clinician chooses the ramp protocol, the VA questionnaire is helpful for estimating  $\dot{V}o_2$  max in METs; most clinicians program the equipment to reach maximal METs in about 10 minutes.

With additional equipment that measures expired gases (e.g., oxygen, carbon dioxide) and total ventilation, the clinician can do four things: (1) actually measure the maximal aerobic capacity; (2) determine the anaerobic threshold (i.e., the point during exercise when marked lactic acid production begins); (3) give a more accurate exercise prescription; and (4) decide if impaired exercise capacity is due to a pulmonary condition or a cardiac cause (more common). Such equipment is becoming smaller and more affordable, which broadens the indications for EET in the office and (some experts say) increases the potential for greater reimbursement (see the "Suppliers" section). To avoid large capital equipment costs, there are service companies that will bring portable equipment to your office for this procedure and split the fees.

# **TECHNIQUE**

- Review the patient's interval medical history and examine the patient. Based on the history and reexamination, make sure no contraindication has developed since the last time the patient was seen.
- 2. Select the mode of EET (e.g., treadmill, bicycle ergometer, arm ergometer), based on the individual's ability to exercise.
- 3. Select the protocol.
- 4. Obtain the resting BP.

TABLE 93-2 Standard Bruce Protocol

MET, metabolic equivalents. From Froelicher VF. Exercise and the Heart: Clinical Concepts, 3rd ed. St Louis, Mosby, 1993.

Figure 93-14 Patient with electrodes attached.

- 5. Prepare the patient for the ECG leads and apply them.
  - Locate sites on the chest for electrode placement, which are the same as for the office ECG (see Chapter 89, Office Electrocardiograms), except that the arm electrodes are placed in the infraclavicular fossae (mid-clavicle) and the leg electrodes are placed on the lower abdomen above the beltline (Fig. 93-14).
  - Cleanse the skin at these sites with an alcohol prep and let the sites dry thoroughly.
  - Shave any hair from the electrode sites. The cornified outer layer of skin should then be removed with gentle dermabrasion. Fine sandpaper or other abrasives are usually provided in the preparation kit for this purpose.
  - Apply electrodes to these sites.
  - Attach lead wires from the octopus to the appropriate electrodes. (An ECG octopus is the set of leads usually provided by the equipment manufacturer.)
  - Stabilize the EET octopus with a belt around the patient's
    waist. The octopus can be bundled and affixed to the patient
    with extra expansion loops to allow variation in distance
    from the ECG machine and to minimize motion artifact.
    Fortunately, most equipment is now digital and can use filters
    to minimize motion artifact.
  - If desired, for female patients, a gown or loose-fitting shirt can be worn over the lead wires. Jog bras work well; bras with underwire should be avoided.
- 6. Obtain the supine, resting ECG. Because a recent MI is a contraindication to EET, if there is even the remote chance of a recent MI or an interval MI since the last clinician visit, a routine ECG must be repeated. For maximal diagnostic sensitivity, this supine routine ECG should be obtained with the leads in the standard limb positions to allow for comparison with any prior standard ECGs. If this ECG reveals no changes, the limb leads can then be moved back to the exercise positions to obtain the baseline supine preexercise ECG.

NOTE: In an occasional patient, hyperventilation alone will produce ST segment depression. Because patients naturally hyperventilate during exercise, if there is ST segment depression during the procedure, it may be difficult to determine whether hyperventilation caused it or if there is true ischemia. However, hyperventilation artifact is rare enough that most authorities now recommend hyperventilating only those patients with a positive EET, after recovering them, to determine if hyperventilation caused the ST segment deviation. This technique of hyperventilating only those patients with a positive result saves not only time but expense, including the expense of ECG paper. This method is especially effective in the office setting, where fewer positive results typically occur.

# Treadmill EET

Have the patient stand and obtain an ECG. This is the resting standing ECG, which becomes the baseline ECG. If the equipment is digital, it will often take 15 to 20 seconds to acquire the resting standing ECG. During this time, the equipment is acquiring an average of 15 to 20 seconds of ECG tracings to provide the "signal average" that it measures against for later comparison.

**NOTE:** Occasionally, ST segment depression is provoked by having the patient stand. Therefore, the isoelectric standard to measure against for ST segment depression during exercise is the resting standing baseline ECG before the EET.

8. Begin the EET using the selected protocol. Try to discourage the patient from gripping the handrail during the study because this will falsely elevate the maximal exercise capacity; it may also increase ECG artifact and falsely elevate BP. Time may be saved if staff demonstrates the procedure and allows the patient to practice before the clinician arrives. Staff should show the patient how to rest two fingers or the wrists on the handrail while walking near the front of the treadmill and looking straight ahead. (If the patient looks down, dizziness often results.)

# **Bicycle Ergometer EET**

- 7. After completing steps 1 through 6 for treadmill EET, have the patient sit on the bicycle and obtain a sitting ECG.
- Begin the EET using the preselected protocol. The usual protocol starts at 25 W of resistance and increases by 25 W every 2 minutes.

# For Both Treadmill and Bicycle Ergometer EET

- 9. Monitor and record the patient's symptoms, overall condition, heart rate, and ECG at all times. *Instruct the patient to try to give adequate warning before he or she needs to stop the test.* With the exception of submaximal testing, encourage the patient to go as far and as long as possible.
- 10. Record a 12-lead ECG at the end of each stage, at any time an abnormality is noted on the monitor, immediately on stopping, and every minute postexercise during recovery.
  - NOTE: Real data are obtained only from a hard copy of the 12-lead ECG. The monitor merely provides ongoing information, estimates of ST segment changes, and allows the clinician to monitor for arrhythmias. If there is any question regarding ST segment changes, print a hard copy for measurement and interpretation.
- 11. During each stage, at the start of the final minute, ask the patient if there is any chest discomfort, at what point he or she has reached on the PES, and whether he or she wants to continue into the next stage. Also record the BP and heart rate near the end of each stage or at the time of any problems.
  - NOTE: For most patients, their perceived exertion (see Box 93-1) is reproducible at a given level of exercise and tracks fairly linearly with their heart rate. Ask patients to indicate on a scale of 0 to 10 how hard they feel they are working with each stage. On the average, most patients feel they increase by 2 to 3 on the PES with each stage in the early part of the study. PES then usually increases more rapidly, from 7 to 9, near the end of the study. Rarely will anyone declare a 10. Individuals with good perception may not have to measure their pulse as frequently while following their exercise prescription. They can simply be instructed to exercise to the level of perceived exertion that matched their appropriate heart rate for the aerobic range (60% to 80% MHR). On the other hand, patients who highly underestimate their effort must be taught to measure their pulse before receiving an exercise prescription.
- 12. After completion of the EET, if it has been done for diagnostic purposes and the study has been negative, immediately ask the

- patient to lie down. Although this may not be comfortable for certain patients, especially if they are overweight or having slight difficulty breathing, it minimizes false-positive results during the recovery. Make sure to record the heart rate at 1 minute (HRR).
- 13. If the EET is positive or being performed for CAD management purposes, keep the patient exercising for 3 to 4 minutes during recovery at a very low workload to prevent venous pooling and to minimize the risk of an arrhythmia. The patient may then either sit or lie down for the remainder of recovery.
  - **NOTE:** For positive studies—even for those profoundly positive—very rarely is it necessary to administer medications. Simply stopping the exertion and having the patient sit up to improve oxygenation should be adequate. If there is strong suspicion that a plaque has been destabilized (MI has occurred), aspirin, if not contraindicated, is the best choice for a medication. In the absence of contraindications, oxygen may also be considered. Sublingual nitroglycerin is risky in a vasodilated patient because it may drop the BP. Sublingual calcium channel blockers are contraindicated.
- 14. Monitor the BP, heart rate, any symptoms, and the ECG tracing during recovery.
- 15. The patient should be monitored for at least 8 minutes in recovery or until symptoms or ECG abnormalities have resolved (some clinicians monitor only for 4 minutes postexercise for negative EETs in low-risk patients, such as those being tested as part of a wellness program).

# **Test Termination Criteria**

A good rule of thumb for stopping an EET is *after* the necessary information is obtained and *before* there is a complication. In the young or fit individual, when he or she reaches the predicted MHR (220 – age), it may be prudent to explain that all the necessary information has been obtained; however, the patient may continue to exercise for as long as he or she desires. (Allowing the patient to make this choice is also indirectly obtaining informed consent.)

**NOTE:** In the past, authorities denoted two possible definitions of a maximal EET: (1) achieving a target heart rate of greater than 85% of the predicted MHR for that patient's age (i.e., roughly 85% of 220 – age); or (2) exercise to the point of symptoms or maximal voluntary fatigue. Most authorities now encourage patients to exercise to the point of symptoms or maximal voluntary fatigue.

Predicted MHR (220 – age) is not patient specific and is frequently a poor prediction. The only contraindications to going to the point of symptoms are for debilitated or elderly patients or if a submaximal test is indicated. Maximal voluntary fatigue/maximal effort is usually indicated by maximal perceived exertion and the inability to continue at that workload.

Benefits to using the point of symptoms as the end point include the ability to measure true exercise capacity and to determine the patient's true MHR. It also gives the clinician knowledge about a patient's cardiac response at a level of exercise beyond what the patient is likely to reproduce on his or her own. This is certainly reassuring to the clinician when giving an exercise prescription (i.e., it should be safe for the patient to exercise at a lower level of exertion). Disadvantages include discomfort for the patient, especially if he or she is significantly deconditioned.

How does the clinician know if the patient gave a maximal effort? Following the PES is often helpful. Also, an RPP greater than 25,000 generally indicates that the patient has given a good effort. Many other physiologic parameters have been studied in an attempt to predict maximal effort (e.g., heart rate, respiratory rate, BP response), and none has been found to be predictive. However, if patients are aware that it is important to give maximal effort to exclude heart disease, they are usually motivated.

#### Absolute Indications to Terminate a Study

- As exertion increases during EET, if SBP drops below resting standing value, especially after the first minute or two of the EET (most dangerous if it reflects LV dysfunction; in that situation there is a high risk of life-threatening arrhythmias).
- Worsening anginal chest pain (severe enough that the patient desires to stop); it is not prudent for patients to exercise beyond the point where they obtain their "usual" amount of chest discomfort. In other words, there is no reason for the patient to demonstrate his or her worst chest pain while performing the study.
- Central nervous system symptoms (e.g., dizziness, disorientation).
- Signs of poor perfusion (e.g., cyanosis, pallor) or severe ventricular dysfunction (e.g., dyspnea).
- Serious arrhythmias (e.g., three or more premature ventricular contractions [PVCs] in a row [e.g., a salvo, ventricular tachycardia] is an indication to terminate the test), increasingly frequent PVCs associated with ischemia (chest pain or ST segment changes), or atrial arrhythmia with cardiovascular compromise.
- Technical problems with equipment, ECG monitor, or SBP monitoring.
- Marked ECG changes (>3 mm of horizontal or downsloping ST segment depression, or 1 mm of ST segment elevation).
- When maximal voluntary exertion/maximal effort has been attained.
- Patient wants to stop the test (especially elderly patients, where there may be little warning of a complication about to happen).

#### Relative Indications to Terminate a Study

- Worrisome ST or QRS segment changes (e.g., excessive junctional depression, marked axis shift)
- Significant fatigue, shortness of breath, wheezing, leg cramps, or intermittent claudication
- Worrisome appearance (especially important in the elderly, where stability can deteriorate very rapidly; poor perfusion may be indicated solely by a loss of color in an elderly patient)
- Elevated BP (SBP >250 mm Hg, DBP >120 mm Hg)
- Less serious dysrhythmia, including supraventricular tachycardia
- Development of a bundle branch block pattern that cannot be distinguished from ventricular tachycardia or an ST segment elevation MI

#### INTERPRETATION

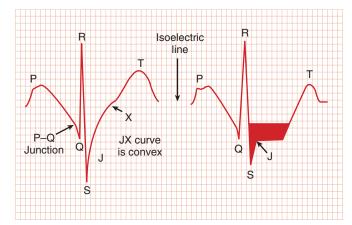

### **Incomplete Exercise ECG Tests**

Failure to attain at least 85% of the age-predicted MHR is an incomplete EET.

Medications (e.g., beta blockers, rate-limiting calcium channel blockers) are a common cause of this; therefore, another reason to withhold such medications is if the EET is being performed for diagnostic purposes. If the EET is being performed to manage CAD, use of beta blockers may increase the patient's exercise capacity, which is also a goal of cardiac rehabilitation. One hopes that increased exercise capacity is a surrogate marker for improved prognosis. If the EET is being performed for diagnostic purposes and the incomplete EET is not deemed due to a medication, options at this point include an exercise imaging test, a chemical (e.g., regadenoson, adenosine, dipyridamole, dobutamine, arbutamine; see Chapter 94, Stress Echocardiography, for a dobutamine echo protocol) imaging test, cardiology consultation, or getting the patient on an exercise program and repeating the EET in 3 to 6 months. Given the choice, many patients will choose to start an exercise program.

# **Normal ECG Responses to Exercise**

- P-wave amplitude increases.
- T-wave amplitude often increases.

**Figure 93-15** Left, Normal exercise ECG complex. Note that the P-Q junction is deflected below the resting isoelectric line. This point is considered to be the baseline for determining ST segment deviations. Right, A horizontal ST segment depression of 2.0 mm as measured from the P-Q junction. (From Ellestad MH: Stress Testing: Principles and Practice, 4th ed. Philadelphia, FA Davis, 1996.)

- RR and PR intervals decrease in length.
- Below a heart rate of 150 bpm, the R-wave amplitude is unchanged or increased; above 150 bpm or near maximal exercise, the R wave in a healthy heart usually decreases in amplitude, and the overall QRS amplitude also usually decreases, especially in the lateral leads (the so-called Brody effect).
- J-point (i.e., the junction between the S wave and ST segment) is depressed in the lateral (possibly all) leads, especially at maximum exercise, and gradually returns to normal during recovery. The P-Q junction is also usually depressed (Fig. 93-15).
- ST segment slope is usually upsloping; however, from the J-point, the tracing rapidly returns to baseline. In other words, at 0.04 to 0.06 second after the J-point, the final position of the ST segment is at the baseline level.

### **ST Segment Analysis**

- A positive EET is determined by ECG criteria. However, the EET results should not be labeled simply as normal, positive, or abnormal, but rather the specific responses to exercise should be identified and documented.
- Age and risk factors for CAD should be taken into account when interpreting results.
- Many conditions and circumstances can cause a false-positive or a false-negative EET (Box 93-4).
- The lateral leads (e.g.,  $V_4$ ,  $V_5$ ,  $V_6$ ) are the most important leads to monitor for ischemia. Their electrodes are located directly over the left ventricle and are the most likely to show ischemic ST segment changes. Although it is always recommended to use at least three leads, studies have found that lead  $V_5$  is the most sensitive lead if a single lead were to be used.

**NOTE:** The actual data are the hard copy printouts of the 12-lead recordings. It is recommended that these be interpreted separately, in a quiet room, scanning the entire printout, before giving the patient the results and recording them.

1. An EET is considered positive when 1 mm of ST segment depression occurs in at least three beats in a row, in more than one lead, and in an area of the tracing where the baseline is relatively flat. If it is truly positive, ST segment depression usually occurs in almost all of the leads; in most cases it will continue more than 1 minute into recovery. In fact, the ST segment depression may worsen in recovery, especially if the patient is asked to lie

# Box 93-4. Causes of False-Positive and False-Negative Test Results

#### Causes of False-Positive Test Results

Preexisting abnormal resting ECG (e.g., ST segment abnormalities and bundle branch block, especially left bundle branch block)

Cardiac hypertrophy (LVH)

Female sex (see section on "ST Segment Analysis in Women," under "Interpretation")

Wolff-Parkinson-White syndrome and other preexcitation variants

Short PR interval

Anemia, hypothyroidism

Hypertension (poorly controlled)

Hyperventilation

Medications (e.g., digitalis, estrogen, tricyclic antidepressants)

Nonfasting state

Cardiomyopathy

Hypokalemia and other electrolyte abnormalities

Hypoxemia

Vasoregulatory abnormalities

Excessive rate–pressure product (>45,000)

Sudden intense exercise

Mitral valve prolapse syndrome and valvular heart disease

Congenital heart disease

Pericardial disorders

Ventricular pacemaker

Pectus excavatum

Inadequate recording equipment, incorrect criteria, improper interpretation, or improper lead system or placement

Technical or observer error

Atrial repolarization (usually seen in inferior leads only, and short PR interval occurs on resting ECG)

#### Causes of False-Negative Test Results

Right bundle branch block

Failure to reach an adequate exercise workload Insufficient number of leads to detect ECG changes

Failure to use other information (e.g., systolic blood pressure drop, symptoms, arrhythmia, heart rate response) in test interpretation

Single-vessel disease

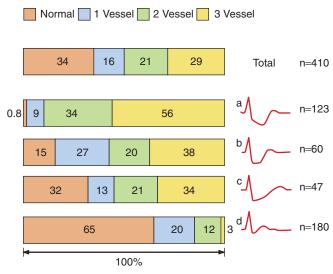

Excessive digital filtration on tracing

Technical or observer error

Medications (tricyclic antidepressants; also medications like long-acting nitrates, beta blockers, and calcium channel blockers have antianginal effects; they may "prolong the positive" or prolong the time of the study before the test becomes positive)

down immediately after exercise is discontinued (recommended if EET is being performed for diagnostic purposes).

- 2. ST segment deviation (depression or elevation) should be measured down or up from the level of the PQ junction. A line drawn horizontally from the PQ junction denotes the isoelectric line (see Fig. 93-15).
- 3. ST segment deviation (depression or elevation) should be measured at the J-point (i.e., ST zero, also known as the beginning of the ST segment or end of the QRS complex).
- 4. Most experts now consider the study positive only if the slope for 80 msec after the J-point is horizontal or downsloping. The ACC/AHA guidelines suggest this is the best definition of a positive EET. Other experts also consider a slow upsloping ST

**Figure 93-16** Three patterns of ST segment depression. Although the downsloping pattern, *a*, usually represented three-vessel disease (56%) and the flat pattern, *b*, occasionally represented three-vessel disease (38%), the slow-uploading pattern, *c*, had three-vessel disease in 34% and at least one-vessel disease in 68% (these usually convert to flat or downsloping in recovery). The rapid-upsloping pattern, *d*, has been accepted as the normal physiologic pattern. (Redrawn from Goldschlager N, Selzer A, Cohn K: Treadmill stress tests as indicators of presence and severity of coronary artery disease. Ann Intern Med 85:277–286, 1976.)

segment pattern as positive, although this was based on much older data from the 1970s (Fig. 93-16). They will consider a slow upsloping pattern positive if the tracing fails to reach within 1.5 mm of the baseline level of the PQ junction at 80 msec after the J-point. It should be understood that although a slow upsloping pattern may be positive, it is much more likely to be a false-positive result or represent insignificant CAD; however, accepting this pattern as a possible positive result slightly increases the sensitivity of the test for CAD. Therefore, increased sensitivity must thus be weighed against the increased likelihood of a false-positive result. A slow upsloping pattern is more likely to be a true-positive result if it persists beyond 1 minute into recovery and is seen not only in the inferior leads (i.e., II, III, aVF), but in other leads. If the proper technique of immediately laying the patient down during recovery is followed, slow upsloping ST segments that truly represent ischemia usually convert to flat or downsloping ST segments with depression.

- 5. Although occasionally ST segment elevation (i.e., transmural ischemia) can indicate the vessel involved, ST segment depression does not localize ischemia. In other words, it cannot detect which blood vessel is involved. Subendocardial ischemia is a "global" phenomenon (i.e., for significant CAD, ST segment changes will be seen in most leads).
- 6. If ST segment elevation occurs over or adjacent to diagnostic Q waves, it may be caused by a ventricular aneurysm or a wall motion abnormality. If it occurs in a patient with a normal resting ECG or without a history of previous infarction, it probably indicates transmural ischemia and the test should be stopped. Transmural ischemia is extremely arrhythmogenic.
- 7. If downsloping or flat-pattern ST segment depression occurs, and it is less than 1 mm or only in recovery, it may be indicative of early CAD. This is an "equivocal" result. Management options are discussed in a following section.

# EET Indicators of Significant or Extensive CAD (Three-Vessel CAD with LV Dysfunction or Left Main CAD)

 Markedly positive ST segment response in multiple leads (>2.5 mm downsloping or horizontal ST segment depression)

- Early positive ST segment response (stage 1 or 2 of Bruce protocol or at ≤4 to 5 METs)
- Unable to complete stage 2 of Bruce protocol (especially if unable to complete stage 1)
- Typical angina chest pain, especially if associated with ST segment depression
- Worrisome ventricular arrhythmias (especially if associated with ST segment depression or at a heart rate <130 bpm)</li>
- Fall in exercise SBP (>10 mm Hg below resting standing baseline), especially when associated with angina or significant ST segment changes
- Prolonged positive ST segment response (>6 minutes of recovery)

# ST Segment Analysis in Special Situations

#### **Baseline Abnormalities**

When the ST segments are abnormal on the resting ECG, certain criteria can be used to declare a test positive (Table 93-4).

#### ST Segment Analysis in Women

False-positive results are less common in women older than 50 years of age. The following data are from a study by Pratt and colleagues (1989).

- 1. True-positive results are associated with four factors:
  - Absence of mitral valve prolapse
  - An exercise duration of less than 5 minutes
  - The ability to reach the target heart rate
  - The ST segment takes 6 minutes or more to normalize
- 2. False-positive results are associated with two factors:
  - The ability to exercise to stage 3 of the Bruce protocol
  - Rapid (<4 minutes) normalization of the ST segment shift after cessation of exercise

**NOTE:** In general, if slow upsloping ST segments are used to define a positive EET, they are associated with a high false-positive rate in women. If the proper technique of laying the patient down during recovery is followed, slow upsloping ST segments that truly represent ischemia usually convert to flat or downsloping ST segments with depression.

# Scenarios with Decreased Sensitivity and False-Positive and False-Negative Results

 If LBBB or WPW syndrome is present, ST segment depression does not necessarily indicate ischemia.

# **TABLE 93-4** Recommended Criteria to Declare an EET Positive When There Are Baseline ECG Abnormalities

Abnormal Resting ST Segment T-Wave Configuration	Exercise or Postexercise ST Segment Configuration	ST Segment Depression and Point of Measurement
Flat or sagging ST segment and T wave	Horizontal	1.0 mm more depressed than at rest
	Upsloping	1.5 mm more depressed than at rest at 80 msec from J-point
	Downsloping	1.0 mm more depressed than at rest
Inverted T wave	Horizontal Upsloping Downsloping	1.5 mm at 60 msec from J-point 1.5 mm at 80 msec from J-point 1.5 mm at 20 msec from J-point

Note that these current criteria are slightly different depending on the configuration of the resting ST segment and T wave.

From Ellestad MH: Horizontal and downsloping ST segments. In Stress Testing: Principles and Practice, 4th ed, Philadelphia, FA Davis, 1996.

- If RBBB is present, the ST segments can be analyzed only in V<sub>4</sub>,
   V<sub>5</sub>, or V<sub>6</sub>, and the sensitivity of the test may be decreased.
  - **NOTE:** Recent data indicate that the presence of complete RBBB on the resting ECG is associated with a 50% greater risk of death over the next 20 years, a rate similar to that of LBBB. The mechanism underlying the relationship is unclear.
- If ST segment depression occurs only in inferior leads II, III, or aVF and not in the lateral leads, it is usually a false-positive result caused by atrial repolarization. When reviewing, these patients frequently have a short PR interval on the resting ECG (the atrial repolarization wave, which is negative, "pulls down" the ST segment when superimposed). Frequently, the ST segment depression returns to normal in less than 1 minute of recovery in the false-positive cases.
- If coronary artery bypass surgery has been performed, sensitivity
  of the test may be decreased.
- If anterior or lateral Q waves or both are present (after MI), the sensitivity of the test may be decreased.
- See Box 93-4 for a complete listing of causes of false-positive and false-negative test results.

# **Arrhythmias**

- Prognosis in supraventricular and ventricular arrhythmias appears to be more related to underlying or coexisting conditions, especially ischemia. Patients who are symptomatic should be treated or referred.
- If the arrhythmia is associated with signs or symptoms of ischemia, in most cases management should be directed at treating the ischemia to minimize the arrhythmia.
- PVCs are common. They are ominous only in patients with LV dysfunction, severe ischemia, valvular heart disease, a cardiomyopathy, or a family history of sudden cardiac death.
- Three unifocal PVCs in a row is defined as a "salvo" and an indication to terminate the test. Interestingly, asymptomatic, nonsustained ventricular tachycardia in an individual with a

- normal ejection fraction is not associated with increased cardiovascular mortality. However, a Holter monitor, echocardiogram, or both may be indicated.
- Young (i.e., <40 years of age) but otherwise healthy individuals
  with no CAD risk factors may have frequent PVCs at rest that
  resolve with exercise. If the EET is negative, further evaluation
  is often not necessary. PVCs that go away with exercise in this
  population are almost always benign.</li>

# **Exercise Capacity and Heart Rate Recovery**

- The ability to achieve 15 METs indicates an excellent prognosis, even in those with known three-vessel CAD. The ability to achieve 10 METs indicates that medical management is reasonable, even in patients with a positive EET. An inability to achieve 5 METs indicates a poor prognosis, especially if the EET is positive.
- VO<sub>2</sub> max can be estimated from various exercise protocols using standard formulas, tables, or graphs. Using estimated VO<sub>2</sub> max, an individual's approximate level of aerobic conditioning can be determined using age- and sex-matched tables. Figure 93-17 also estimates the exercise capacity based on the number of METs a patient can achieve.
- Failure of the heart rate to decrease 12 bpm in the first minute of recovery is an abnormal HRR. This indicates a fourfold increased risk of mortality over the next 5 years.
- As mentioned previously, in patients where ECG changes during EET could not be used to predict prognosis (e.g., baseline ECG abnormalities, digoxin use)—in other words, the DTS could not be used—Diaz and colleagues (2001) at the Mayo Clinic found exercise capacity and HRR to be better predictors of risk over 6.7 years than radionuclide imaging in nonrevascularized patients.

#### Other Parameters Followed

 Heart rate: Failure to obtain a heart rate of 120 bpm is chronotropic incompetence with a resultant poor prognosis

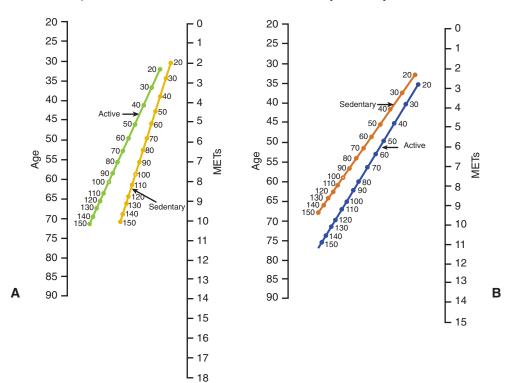

Figure 93-17 Nomograms of percentage normal exercise capacity. A, Percentage of normal in healthy men. B, Percentage of normal in referred men. (Redrawn from Kenney WL [ed]: ACSM's Guidelines for Exercise Testing and Prescription, 5th ed. Baltimore, Williams & Wilkins, 1995.)

(approximately 15% per year will experience a coronary event); it may also indicate early sick sinus syndrome.

 BP: As exertion increases during EET, if the SBP drops below resting standing baseline, it predicts either a poor prognosis or severe CAD. In one study, men with a maximal exercise SBP of less than 140 mm Hg also had a 15-fold increase in the annual rate of sudden death compared with those whose pressures exceeded 200 mm Hg.

A DBP increase of more than 10 mm Hg, an SBP greater than 214 mm Hg, or failure of DBP and SBP to return to normal 3 minutes into recovery is a *hypertensive response to exercise*. In otherwise healthy individuals, a hypertensive response to exercise increases the likelihood that they will develop hypertension over the next few years. However, EET should not be used to screen for hypertension because ambulatory BP monitoring is much more effective. In individuals with known hypertension, a hypertensive response to exercise may indicate poorly treated hypertension. Poorly treated hypertension may have a negative impact on exercise tolerance.

- BP and heart rate in diabetic patients: Diabetes can cause an elevated resting heart rate; BP and heart rate responses are frequently blunted in diabetic patients.
- Symptoms: Substernal chest pain in men being tested on a treadmill, even without ECG changes, is 90% predictive of CAD in studies from a few decades ago.
- Lack of symptoms: Painless ST segment depression (i.e., silent ischemia) is common in diabetic patients and those older than 70 years of age.

#### **DETERMINING PROGNOSIS**

# Normal ECG Responses and Negative EET (Prognosis Is Excellent)

- Absence of any change in the ST segment at maximal or near MHR
- Junctional or J-point depression with rapidly rising ST segment slope.
- Development of isolated T-wave inversion without ST segment displacement.
- Ventricular ectopic beats occur infrequently, especially those occurring at heart rates exceeding 130 bpm and not associated with any evidence of ischemia.
- Although rare, even a poorly controlled atrial arrhythmia without cardiovascular compromise has a good prognosis.
- Although rare, development of RBBB with exercise has a good prognosis.

Patients can be reassured that if they achieve a heart rate of 160 bpm (regardless of age) and achieve 13 METs (basically equivalent to completing 12 minutes on the Bruce protocol), even with ECG evidence of ischemia, they have a very good 4- to 5-year prognosis. They basically have less than a 1% per year risk of a cardiac event for that time span. The same is true if they achieve an RPP greater than 35,000; they are extremely unlikely to have significant CAD. Even for positive studies, periodic evaluation with a retest in 6 to 12 months may be the most aggressive management needed.

If patients are unable to achieve these end points, it may indicate either inadequate effort by the patient or the presence of CAD. For a strong clinical suspicion of disease, additional testing such as imaging or angiography should be considered.

#### **Positive and Abnormal EETs**

To obtain prognosis data for abnormalities of heart rate or blood pressure, see "Other Parameters Followed" in the previous section. Otherwise, prognosis is poor for patients unable to achieve 5 METs

or for patients demonstrating a positive EET at less than 5 METs. For those patients in whom an intervention is appropriate or if the clinician is unsure of the diagnosis, prognosis, or management, a cardiologist should be consulted.

For those patients with a positive EET and able to achieve 5 METs, a heart rate of 120 bpm, and an RPP of more than 25,000, a nomogram is available for determining prognosis, counseling, and follow-up. As opposed to other similar nomograms available, women (although not as many) were included in the studies resulting in the nomogram in Figure 93-18. Therefore, this nomogram can be used when counseling women.

Most large coronary artery bypass surgery centers have known or published complication rates. The AHA's website (www.americanheart.org) also has excellent data for predicting complications from coronary artery bypass surgery. Using the nomogram (see Fig. 93-18), patients can evaluate their annual risk of a cardiovascular event with medical management versus a surgical intervention. These are very powerful tools for what is usually a very important decision for patients to make.

Based on several studies, for patients with CAD and able to achieve 10 METs, which is basically the level of exertion necessary to complete approximately 9 minutes of a Bruce protocol, medical management is prudent or reasonable. It is also very unlikely that these patients have significant disease if they achieve a RPP of 25,000 or greater. With an outstanding exercise capacity, even patients with multivessel CAD do well. One study revealed that in patients with known three-vessel CAD and able to complete 15 minutes of a Bruce protocol, the 5-year survival rate was 100%.

#### **COMPLICATIONS**

- Hypotension
- Congestive heart failure exacerbation
- Severe cardiac arrhythmia
- Cardiac arrest
- Acute MI
- Acute central nervous system event, such as syncope or stroke
- Death

**NOTE:** The overall safety of EET has been confirmed with multiple studies. For patients being tested on a treadmill, the mortality rate is approximately 1 in 10,000. The hospital admission rate related to arrhythmia, prolonged chest pain, or MI is approximately 4 in 10,000. However, it should be noted that these numbers include patients with known CAD, perhaps even taking antiarrhythmics. A much smaller risk can be maintained if patients are selected carefully, which is what must be done for office testing.

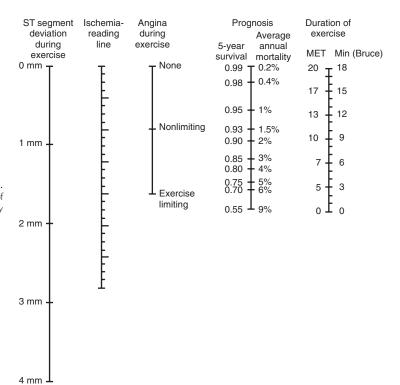

# POSTPROCEDURE PATIENT EDUCATION

Patients should be informed that EET, just like any other non-invasive study for diagnosing CAD, is not 100% accurate. Individuals with a change in symptoms or symptoms of chest discomfort, palpitations, or any other symptoms that could be caused by CAD should be evaluated by their clinician regardless of the result of the EET.

In patients with CAD or a high probability of CAD, counseling should be directed at modifying risk factors. Exercise prescriptions should be given and discussed.

#### Giving an Aerobic Exercise Prescription

 Exercise capacity or endurance is increased by performing regular (i.e., three episodes per week) aerobic exercise. For primary prevention, although a fourth episode further increases exercise capacity, after the fourth per week the incremental benefit is less.
 The greatest benefit of additional episodes of exercise per week

**Figure 93-18** Nomogram for Duke University Prognostic Score. (Redrawn from Mark DB, Shaw L, Harrell FE, et al: Prognostic value of a treadmill exercise score in outpatients with suspected coronary artery disease. N Engl J Med 325:849–853, 1991.)

is to assist with weight loss. For secondary prevention, there continues to be improvement in exercise capacity with additional episodes per week. Consequently, most cardiac rehabilitation programs recommend exercising most days of the week for an hour a day.

- For primary prevention, aerobic exercise can be performed 3 days
  in a row to maintain fitness; however, the risk of an injury
  increases without adequate rest between episodes. It is therefore
  recommended that individuals exercise, at an aerobic level, every
  other day. Participating in a less intense walking program on
  intervening days may also assist with weight loss.
- Aerobic exercise involves raising the heart rate to a specified point (60% to 80% of MHR) and maintaining that level of exercise for 30 to 45 minutes per session. Three 10-minute episodes in the same day accomplish the same effect as one 30-minute episode.
- After EET, a safe aerobic training range is at a heart rate of 60% to 80% of MHR. This range is called the *target heart rate*. A PES of 5 to 7 can also be used in most patients; however, some patients have a poor perception of level of exertion, and therefore PES cannot be used.
- Patients should avoid dehydration and weather extremes. Unlike what was done if the EET was performed for diagnostic purposes, they should warm up and cool down after each episode, especially older patients.
- A repeat EET can evaluate the improvement after implementation of an aerobic exercise program. After introduction of an exercise program, it takes approximately 12 weeks of regular exercise to achieve a new level of exercise capacity.
- To avoid boredom, it is recommended that an exercise prescription include more than one kind of aerobic exercise (e.g., swimming, biking, race walking, jogging, aerobic dance).
- An exercise prescription should include a target heart range or level of PES, duration of exercise sessions, frequency of sessions, and types of exercises that can be used to achieve the goals of cardiovascular conditioning (aerobic). For new exercise prescriptions, the rate of progression needs to be explained.

 Competitive athletes want to use their training program to raise their anaerobic threshold (i.e., level of exercise at which they can no longer oxygenate all tissues). Anaerobic thresholds are now best measured with ventilator-expired gas analysis EET.

#### **PATIENT EDUCATION GUIDES**

See the sample patient consent form available online at www. expertconsult.com.

#### **CPT/BILLING CODES**

93000 Electrocardiogram, routine ECG with at least 12 leads; with interpretation and report

93015 Cardiovascular stress test using maximal or submaximal treadmill or bicycle exercise, continuous ECG monitoring, and/or pharmacologic stress; with physician supervision, with interpretation and report

93016 Physician supervision only, without interpretation and report

93017 Tracing only, without interpretation and report

93018 Interpretation and report only

### **ICD-9-CM DIAGNOSTIC CODES**

- 412 Old MI (healed; past MI diagnosed on ECG, but currently no symptoms)
- 413.9 Other and unspecified angina pectoris
- 414.01 Coronary atherosclerosis, of native coronary artery
- 414.02 Coronary atherosclerosis, of autologous vein bypass graft
- 414.04 Coronary atherosclerosis, of artery bypass graft
- 414.05 Coronary atherosclerosis, of unspecified type of bypass graft
- 414.8 Chronic coronary insufficiency
- 427.69 Ventricular premature beats, contractions, or systoles
- 785.1 Palpitations
- 786.51 Precordial chest pain

# STRESS ECHOCARDIOGRAPHY

Grant C. Fowler • Al Smith

Although one of every three deaths (more than half a million deaths a year) in the United States is caused by coronary artery disease (CAD), which is the leading cause of death in both genders, we are doing a better job at keeping these patients alive. Consequently, primary care clinicians will continue to manage an increasing number of patients with known CAD. Not only is stress echocardiography ("stress echo") a safe, cost-effective, and noninvasive method for diagnosing CAD, but it is also helpful for managing CAD, including determining the prognosis. Some clinicians also use stress echo to screen high-risk asymptomatic individuals or to stratify risk in preoperative evaluations. With medical management of CAD more successful than ever, primary care clinicians' skills in diagnosing and managing CAD have become more important. Performing stress echo is one method of maximizing these skills.

With improved ultrasound technology and image quality, adequate imaging can now be produced from 85% to 90% of patients undergoing stress echo. Improved digital imaging recording capabilities are also more likely to provide adequate pre- and postexercise stress echo images for comparison, side by side. The cost of echo equipment has also decreased significantly as the technology has expanded and improved. Consequently, echo has seen some of the most rapid growth among procedures performed by primary care clinicians.

Adding a cardiac imaging test to an exercise electrocardiography (ECG) test (EET) or a pharmacologic stress test is indicated when there is need to define the location, overall extent, or functional significance of CAD. Differing from an EET, which cannot predict which obstructed coronary artery is causing a positive test, stress echo is able to determine which coronary artery is obstructed by noting which ventricular wall becomes ischemic (Table 94-1). Although coronary angiography may not be the best method for determining the functional significance of CAD, it can be used as the gold standard when comparing the accuracy of nuclear myocardial perfusion imaging with stress echo. In the revascularized patient, several meta-analyses compared the accuracy of these two tests for detection of restenosis. Based on results showing very similar sensitivities, specificities, and accuracies for diagnosis of CAD, the choice of imaging for CAD after revascularization will likely depend upon clinician experience and other local factors, such as availability and expertise. Regarding prognosis for patients with CAD, several other meta-analyses compared stress echo with myocardial perfusion imaging and demonstrated comparable results. If echo images are excellent, stress echo may be more accurate than myocardial perfusion imaging.

Further, when evaluating patients for cardiac problems, stress echo can diagnose other possible causes such as hypertrophic cardiomyopathy, aortic dissection, valvular heart disease, diastolic dysfunction, and pericardial effusion, which sets it apart from myocardial perfusion imaging. Stress echo is also faster to complete, is less expensive, and does not require irradiation.

In addition to greater convenience to the patient, benefits for primary care clinicians performing stress echo (especially in the office setting) include having test results immediately available, improving communication and referral patterns to cardiologists, and improving their echo reading skills. Clinicians performing stress echo also naturally improve their understanding of CAD pathophysiology as well as exercise physiology. With immediately available results, patient satisfaction is usually improved and liability for the clinician from failure to diagnose should be decreased.

#### PHYSIOLOGY OF STRESS ECHOCARDIOGRAPHY

Normally, as the heart rate increases with exercise, the walls of the left ventricle increase contractility, increase endocardial excursion (>5 mm), become hyperdynamic, and thicken in systole. Depending upon the exercise protocol utilized, the ejection fraction will also normally increase. Consequently, the end-systolic volume, which is the actual size of the left ventricle at end-systole, decreases. In the patient with obstructive CAD, with increasing exercise, a threshold is eventually reached at which the heart's demand for oxygen exceeds the supply. At this threshold, the heart becomes ischemic, first regionally or in segments, and then often globally. Although it is best to obtain echo images within the first minute of discontinuing exercise, this blunting of wall motion will typically persist for 3 to 5 minutes depending on the severity and duration of the preceding ischemia. Interpretation of a stress echo test consists of quantifying these transient regional wall motion abnormalities (Fig. 94-1) as well as the global function (i.e., ejection fraction/end-systolic volume). Transient ischemia is assessed and quantified by comparing pre- and postexercise echo images. (Depending on the protocol, images are also sometimes obtained at maximal exertion.)

From an ECG perspective, with subendocardial ischemia, the patient usually demonstrates ST segment depression (i.e., a positive exercise EET; see Chapter 93, Exercise Electrocardiography [Stress] Testing) in several leads. Usually this depression is followed by chest discomfort (i.e., angina) as the "ischemic cascade" progresses. The term "ischemic cascade" describes the predictable sequence of events that occur after the onset of ischemia. With stress echo, earlier aspects of this ischemic cascade can be noted. Soon after the metabolic abnormalities are produced from ischemia, diastolic abnormalities appear, and these can be seen with stress echo. The appearance of these abnormalities is rapidly followed by myocardial perfusion defects and, in turn, by wall motion abnormalities again seen on stress echo. In other words, ischemic changes can be seen on perfusion imaging and stress echo prior to the development of ECG changes on EET. Eventually chest pain may develop, the exception being patients who experience so-called "silent angina" (typically patients >70 years of age, possibly earlier in diabetics). In patients with silent angina, dyspnea or dyspnea with exertion is a common presentation of an anginal equivalent.

Because exercise capacity is an important, separate predictor of outcome from a cardiovascular perspective, for those patients able to exercise, exercise echo is recommended over pharmacologic stress echo. For those able to walk on a treadmill, it is probably the preferred mode of exercise testing because the workload achieved as well as the maximal heart rate is usually higher than with a bicycle.

and Corresponding Coronary Artery Supply						
Echocardiographic Segment	Coronary Artery					
Basal, mid-, and apical anterior Basal, mid-, and apical anterior septum Apical lateral Basal and mid-anterolateral Basal and mid-inferior Basal and mid-inferior septum Apical inferior	LAD LAD LAD LAD/LCA RCA RCA RCA RCA/LAD					
Basal and mid-inferolateral	LCA					

LAD, left anterior descending artery; LCA, left circumflex artery; RCA, right coronary artery.

The most common forms of exercise in the United States are walking and jogging, so patients are often more comfortable with a treadmill and it is possibly less effort- or motivation-dependent. However, the maximal blood pressure achieved is usually higher on a bicycle than with a treadmill, and images can be obtained during

exercise and at peak workload with use of a supine bicycle. A bicycle is also often the preferred form of exercise for patients with orthopedic problems.

### **INDICATIONS**

AUTHOR'S NOTE: The American College of Cardiology (ACC)/American Heart Association (AHA) suggest that for the patient capable of exercise with no baseline ECG abnormalities affecting the ability to monitor or interpret an EET (e.g, left bundle branch block [LBBB], digitalis effect, Wolff-Parkinson-White [WPW] syndrome, left ventricular hypertrophy [LVH], >1 mm ST segment depression), EET is the preferred method of evaluation to exclude CAD. Not every patient needs to be evaluated with imaging. Even in the patient with an intermediate pretest probability of disease, the ACC/AHA recommend a stepwise strategy for diagnosing CAD; in these patients, an EET is the preferred initial test. That said, there are plenty of indications for stress echo:

- Detection of CAD.
- Dyspnea possibly due to CAD.

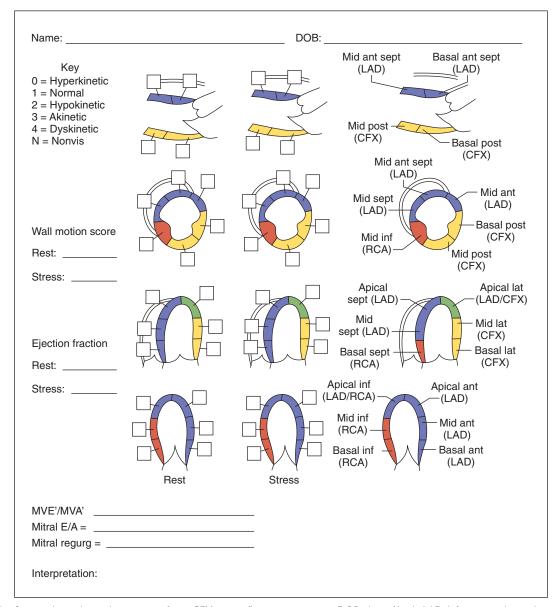

Figure 94-1 Stress echocardiography test score form. CFX, circumflex coronary artery; DOB, date of birth; LAD, left anterior descending coronary artery; MVA', mitral valve annulus velocity; MVE', mitral inflow velocity; RCA, right coronary artery.

- Equivocal, uninterpretable, or suspected false-positive EET.
- High probability of false-positive EET (e.g., women, mitral valve prolapse).
- Baseline ECG abnormalities that would affect the ability to monitor or interpret an EET (e.g., LBBB, digitalis effect, WPW syndrome, LVH, >1 mm ST segment depression).
- New-onset atrial fibrillation or heart failure, especially if there is an intermediate pretest probability of CAD.
- Need to define extent, location, or functional significance of CAD.
- Risk stratification/prognostic assessment in patient with known CAD (preoperative, post–myocardial infarction).

**AUTHOR'S NOTE:** Dobutamine echo is probably the preferred method of evaluating a patient preoperatively for high-risk or vascular surgery. See Box 94-1 for shortcuts to determine indications for noninvasive testing prior to noncardiac surgery. (See also Chapter 230, Preoperative Evaluation.)

- Risk stratification after coronary revascularization (percutaneous coronary intervention or coronary artery bypass graft) procedures.
- Viability assessment in candidate for revascularization.
- Radionuclide perfusion imaging not available.
- High probability of false-positive radionuclide perfusion imaging (e.g., correction software package not available for perfusion imaging when likely to have attenuation artifact due to nearby adipose tissue such as in women or large-chested men).

# Box 94-1. Shortcuts to Determine Indicators for Noninvasive Testing before Noncardiac Surgery

No testing necessary if the answer is Yes to any of these four questions:

- 1. Is this low-risk surgery (e.g., endoscopic, superficial, cataract, breast, ambulatory surgery)?
- 2. Does the patient have fair functional/exercise capacity (≥4 METs) and no symptoms?
- 3. Has the patient undergone revascularization (CABG or PCI) within last 5 years without a change in symptoms indicating ischemia?
- 4. Has the patient had a thorough cardiac evaluation within last 2 years without a change in symptoms indicating ischemia?
- Conversely, if vascular surgery is planned and patient has three or more clinical risk factors (CAD, CHF, ASCVD, diabetes, or renal insufficiency), noninvasive testing is reasonable if the results will change the management.
- Also, if the answer is Yes to both of the following two questions, noninvasive testing is reasonable\*:
- Poor functional/exercise capacity by questionnaire or specific questioning? (<4 METs or inability to climb one flight of stairs)
- 2. Clinical risk factor present? (CAD, CHF, ASCVD, diabetes, or renal insufficiency)

\*For intermediate- or high-risk surgery with only one or two clinical predictors present, there is insufficient evidence to determine the best management—β-blockade therapy versus noninvasive testing. ASCVD, atherosclerotic cardiovascular disease; CABG, coronary artery bypass graft; CAD, coronary artery disease; CHF, congestive heart failure; METs, metabolic equivalents; PCI, percutaneous coronary intervention.

From ACC/AHA: 2007 Guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery. Circulation 116: 1971–1996, 2007.

- Asymptomatic patients with multiple risk factors for CAD, or high-risk coronary calcium score from electron beam computed tomography scan (EBCT) or on ambulatory ECG (Holter or event) monitoring (see Chapter 87, Ambulatory Electrocardiography: Holter and Event Monitoring).
- Incomplete EET (failure to achieve 85% of predicted maximal heart rate; pharmacologic testing may be indicated).
- A pharmacologic agent may be indicated with stress echo (dobutamine, arbutamine preferred for stress echo over vasodilator infusion; vasodilator infusion usually preferred for myocardial perfusion imaging) in patients unable to exercise (e.g., peripheral artery disease, orthopedic problems, low exercise tolerance, contraindications to exercise [acute coronary syndrome with negative serial cardiac markers, equivocal aortic stenosis with low cardiac output]). Vasodilator (e.g., adenosine, dipyridamole, regadenoson) infusion produces only mild to moderate increases in heart rate and a mild decrease in blood pressure.
- Contrast study may be indicated with stress echo if two or more segments are not seen on noncontrast images.
- Permanent or transesophageal pacing may be indicated with stress echo (the pacing rate can be increased until the desired heart rate is achieved; however, these techniques are beyond the scope of this chapter).
- Mitral and aortic valve stenosis and regurgitation can be assessed, usually involving color Doppler (these techniques are beyond the scope of this chapter).
- Careful assessment of aortic stenosis by noting rapid change in pre– and post–aortic valve peak pressures.

Results of a comprehensive, expert survey are available regarding the appropriate use of stress echo. The most common and appropriate indications for primary care clinicians include diagnosing CAD (especially when EET is uninterpretable or equivocal or there is a high risk of a false-positive EET or myocardial perfusion imaging test) and managing CAD (especially when it is necessary to define the extent, location, or functional significance of CAD such as in the revascularized patient). These guidelines also cover special situations in which stress echo is useful (e.g., dyspnea, pulmonary hypertension, valvular stenosis, new-onset atrial fibrillation, or heart failure), especially if combined with intermediate probability of CAD. The use of stress echo often helps sort out whether the symptom or problem is coming from CAD or another source. As previously discussed, clinicians should recall that by the age of 70 (possibly earlier for diabetics), the most common symptom for presentation of an acute myocardial infarction (MI) is dyspnea as opposed to chest pain. This is the so-called "silent angina" or anginal equivalent that patients often develop resulting in dyspnea with exertion.

### **Indications for Diabetics**

Because of a disproportionate burden of CAD in diabetic patients, the American Diabetes Association has suggested indications for cardiac testing in diabetic patients. Although these indications have varied over the years, two indications have persisted:

- 1. Typical or atypical cardiac symptoms
- 2. Abnormal resting ECG (especially if suggestive of ischemia or myocardial infarction)

Many diabetic patients are unable to undergo an EET due to peripheral artery disease or neuropathy. Such patients are generally at higher risk for cardiovascular events than those able to undergo an EET. Dobutamine stress echo has been shown to provide independent prognostic information in this group.

# **Determination of Pretest Probability**

Determining pretest probability may help the clinician decide whether stress echo is the indicated and proper diagnostic procedure. Stress echo is probably not indicated in patients with a low pretest probability of CAD (<10%) if they are able to exercise and have an interpretable electrocardiograph (i.e., absence of baseline ECG abnormalities such as LBBB, digitalis effect, WPW syndrome, LVH, >1 mm ST segment depression).

Pretest probability can be estimated by a description of the chest pain and the patient's gender and age. *Typical angina* is described as substernal, exertional, and relieved by rest or nitroglycerine. Chest discomfort with two of these three characteristics is *atypical angina*. Chest discomfort with only one of these characteristics is considered *nonanginal chest pain*. Using these three descriptions, pretest probability tables and their corresponding graphs (see Table 93-1 and Fig. 93-4 in Chapter 93, Exercise Electrocardiography [Stress] Testing) can be readily applied to determine pretest probability. Determining pretest probability may also be helpful when assessing prognosis.

#### **CONTRAINDICATIONS**

- Unable to obtain adequate resting echo images
- Very recent acute MI (within 2 days) or other acute cardiac event (submaximal testing may be indicated unless patient has undergone angioplasty or stent placement)
- High-risk unstable angina
- Severe symptomatic left ventricular dysfunction or uncontrolled symptomatic heart failure
- Potentially life-threatening or uncontrolled ventricular arrhythmias causing symptoms or hemodynamic compromise
- Third-degree atrioventricular block or second-degree Mobitz type II block without pacemaker
- · Acute pericarditis, myocarditis, or endocarditis
- Severe aortic stenosis, hypertrophic cardiomyopathy, or other form of outflow obstruction (can be excluded by performing echo prior to test)
- Suspected dissecting aneurysm
- Severe arterial hypertension (resting >200 mm Hg systolic or >115 mm Hg diastolic)
- Electrolyte abnormality
- Acute pulmonary edema, embolus, or infarction
- Acute thrombophlebitis, deep vein thrombosis, or intracardiac thrombi
- Acute or serious general illness or infection
- Neuromuscular, musculoskeletal, or arthritic condition that precludes exercise (pharmacologic testing may be an option)
- Uncontrolled metabolic disease, such as diabetes, thyrotoxicosis, or myxedema
- Medication intoxication from drugs such as digoxin, sedatives, or psychotropic agents
- Advanced or complicated pregnancy
- Patient inability or lack of desire or motivation to perform the test, including severe emotional distress
- Nonavailability of advanced cardiac life support (ACLS) equipment or of an individual certified to perform ACLS

**NOTE:** Some of these contraindications are relative. In selected cases, a skilled cardiologist may perform testing for patients with these diagnoses (generally in a referral center). All are contraindications to testing in the office.

### **EQUIPMENT**

- For best images, an ultrasound machine with several probes of varying frequency should be available. Among these probes, a low frequency (e.g., 2.5 MHz) probe with two-dimensional (2D), M-mode, and cardiac Doppler capabilities is necessary. An ultrasound machine with harmonic imaging ensures high-quality images. A method of recording the examination (e.g., server, DVD, VCR) is also needed for documentation.
- Ultrasonic jelly and towels to clean up after scanning.

- Patient gown.
- A treadmill with adjustable speed and grade (see Fig. 93-11 in Chapter 93, Exercise Electrocardiography [Stress] Testing)—this is the most common equipment used for stress echo. Advantages include the ability to test most patients under the actual physiologic conditions of exercise. Disadvantages include the fact that the treadmill may be difficult to use for patients with lowerextremity or lower-back problems or for patients who are very obese. The equipment is also more expensive, causes more motion artifact, and is noisier than a bicycle ergometer.
- Bicycle ergometers (see Fig. 93-8 in Chapter 93, Exercise Electrocardiography [Stress] Testing) use adjustable resistance and pedal frequency to exert the patient. Advantages with the bicycle ergometer include the capability to terminate the test instantly. If a bicycle ergometer is utilized, images can be obtained at peak workload, especially if a supine bicycle ergometer is utilized. These images are especially useful for evaluating diastolic and valvular dysfunction, especially with use of color Doppler. Many patients feel more secure sitting on the bicycle. This method is also associated with less artifact, and blood pressure (BP) measurements are easier to obtain. Unfortunately, in the United States leg fatigue is common because most patients do not bike. In fact, as a result of leg fatigue the procedure often fails to determine  $VO_{2 \text{ max}}$ . Bicycle ergometry is also dependent on motivation throughout its duration. As a result, in the United States if the patient can tolerate the treadmill, most clinicians prefer to use it.
- Arm ergometer (see Fig. 93-9 in Chapter 93, Exercise Electrocardiography [Stress] Testing) enables patients with severe orthopedic problems to be tested. However, muscle fatigue often occurs before the maximum heart rate is achieved.
- ECG machine (see Fig. 93-10 in Chapter 93, Exercise Electrocardiography [Stress] Testing)—A continuous monitor is needed (a three-channel model with continuous tracing and a screenfreeze option is desirable) as well as a 12-lead ECG recorder. With modern equipment, the recorder also runs the treadmill. Most equipment is now digital, allowing data to be filtered to provide a smooth baseline.
- Electrodes, cables, and belt—A disposable or washable belt is preferred because patients usually sweat.
- Sphygmomanometer, including various cuff sizes—A gauge manometer is adequate because the most important readings are those relative to resting pressures (not the absolute pressures).
- Stethoscope.
- Razor, rubbing alcohol.
- Intravenous (IV) setup and medications for pharmacologic testing, if planned, including atropine.
- Emergency equipment (see Fig. 220-4 in Chapter 220, Anaphylaxis) includes a monitor/defibrillator; oxygen; airways, intubation, and suction equipment; and an emergency drug kit containing IV fluids and tubing (available drugs should be able to support ACLS protocols).

All emergency equipment should be checked daily, and medications should be checked weekly to monthly, depending on their use. The exercise testing equipment should be inspected and calibrated periodically, based on manufacturer recommendations. ACLS certification cards should be kept on file along with any other information or written protocols.

NOTE: It is also helpful to have a trained technician assisting (see Fig. 93-11 in Chapter 93, Exercise Electrocardiography [Stress] Testing). Technician certification for exercise testing is available through the American College of Sports Medicine. In many centers the technician prepares the patient; monitors the electrocardiograph and the patient's response to exercise, his or her heart rate, and BP; obtains the pre- and postexercise echo images; and prepares the results for interpretation. For low-risk patients, the technician may actually perform the entire study without a physician being

present. Otherwise, the clinician should examine the patient before, during, and after the procedure; confirm which protocol to use; and terminate the study. The clinician should also monitor the ECG tracing when the technician is taking BP readings, and the clinician should interpret the final results.

#### PREPROCEDURE PATIENT PREPARATION

Before arrival

- The clinician should instruct the patient to minimize alcohol, over-the-counter medications, and caffeine consumption the day before and the day of the procedure. The patient should be encouraged to get a good night's sleep the night before the procedure and should not eat for 2 hours before the test. It might be advisable for the most recent meal to be a small and predominately liquid meal. To minimize the risk of patient fatigue, many clinicians prefer performing exercise testing in the morning. They then instruct the patient to avoid breakfast or to have only a liquid breakfast that day.
- The procedure should be rescheduled, if possible, if the patient has a cold or other viral illness or is not feeling well in general.
- If the indication for the test is to screen for disease or to make the diagnosis of CAD, the clinician should instruct the patient to avoid taking β-blockers the day of the test.

**NOTE:**  $\beta$ -Blockers can suppress the heart rate, diminish segmental wall contractility, and prevent determination of the maximal heart rate (MHR). Patients who discontinue  $\beta$ -blockers should watch closely for "rebound" symptoms and, if they develop, should restart their  $\beta$ -blockers. Because angiotensin-converting enzyme (ACE) inhibitors have little or no effect on performance of a stress test, frequently they may be used as a substitute for other antihypertensive agents. If necessary, they can be taken on the day of the test and usually work within an hour. Clonidine may be used in the same manner.

- If the indication for the test is to determine pharmacologic efficacy in patients with CAD, obviously β-blockers should be taken the day of the study.
- Depending upon the exercise protocol or mode of stress anticipated, the clinician may want to instruct the patient to bring shoes and clothing that are comfortable for walking, possibly for jogging, or for riding a bicycle.
- To minimize patient worry and anxiety (which often cause an elevated resting systolic BP), the clinician should explain that the risk of death for patients being tested using a treadmill is very small (1:10,000 patients). Because exercise testing in an office setting is an elective procedure, patients should never be exposed to excess risk (i.e., patients should be chosen very carefully to ensure that the actual risk of death is much less than even 1:10,000). With dobutamine infusion, the risk of myocardial infarction or ventricular fibrillation is slightly higher, about 1:2,000; however, it has been shown to be safe to use even in patients with left ventricular dysfunction, aortic and cerebral aneurysms, and implantable cardioverter defibrillators.
- With dobutamine infusion, the patient may experience palpitations, nausea, headache, chills, urinary urgency, and anxiety.
   Symptoms related to high or low blood pressure or chest pain may also be experienced. Patients should know it is very rare for the symptoms to be severe enough to stop the test.

#### After arrival

- The clinician should again explain the reasons for the test and answer any questions.
- The procedure should be explained again to the patient (e.g., how frequently the workload will be increased or what to expect with pharmacologic infusion, how BP measurements will be taken, when the echo images will be obtrained, how the perceived exer-

- tion scale [PES] works; see Box 93-1 in Chapter 93, Exercise Electrocardiography [Stress] Testing).
- The patient should be assured of close monitoring and reassured that although the procedure stresses the heart, it is a relatively safe procedure (<1:10,000 mortality rate for exercise, 1:2000 event rate for dobutamine infusion).
- The patient should know what symptoms to report during the test.
- The clinician should explain how the patient can terminate the procedure should he or she have severe symptoms or an emergency.
- A signed, written consent form should be obtained (see a sample consent form [Chapter 93] online at www.expertconsult.com).
- Confirm the mode of exercise (e.g., treadmill, bicycle ergometer, arm ergometer) or method of evoking stress (e.g., pharmacologic), based on the individual's ability to exercise or any contraindications to exercise.
- If using exercise, select the protocol. There are many excellent protocols in use; therefore the choice is often dependent on the patient's predicted exercise capacity and on clinician preference. The Veterans' Administration (VA) Specific Activity Questionnaire (see Fig. 93-1 in Chapter 93, Exercise Electrocardiography [Stress] Testing) may be very helpful for predicting exercise capacity and helping decide between a standard protocol and a less aggressive, modified protocol. One MET is the amount of oxygen consumed while sitting quietly at rest, or basal oxygen consumption, and it can be used as a conversion unit for exercise capacity (e.g., 2 METs is an exercise capacity that consumes twice the amount of oxygen as basal consumption). If the patient can walk up a flight of stairs, he or she has an exercise capacity of approximately 4 METs. If the patient can walk up a flight of stairs carrying a sack of groceries, he or she can probably tolerate a regular protocol. Otherwise, a modified protocol will probably be necessary. Choose a protocol that starts at a low level of exertion (2 to 3 METs).
  - A protocol with stage durations of at least 3 minutes (2 minutes for bicycle ergometer) allows more physiologic adaptation to the workload of each stage.
  - Workload increases that are no greater than 1 to 3 METs per stage also allow more physiologic adaptation.

The Bruce protocol (see Table 93-2 in Chapter 93, Exercise Electrocardiography [Stress] Testing) is the most frequently used protocol with stress echo; overall, it has been the most extensively studied and validated. The number of METs the patient will achieve is about the same as the number of minutes an individual can complete on the Bruce protocol. It is especially useful in active patients and takes less time than other protocols because it rapidly increases workload. It does have its disadvantages: By the fourth or fifth stage, the patient usually must run, which increases artifact on the EET. In addition, the patient often experiences difficulty in accommodating increases to both slope and speed at the same time. This difficulty is especially seen in elderly patients because they usually have decreased proprioception in their toes and some degree of impairment of vision. In general, most "modified" protocols, such as the modified Bruce or modified Balke protocol, have a reduced progression of workload and are better tolerated by elderly or debilitated patients. Modified protocols usually maintain the same speed and only vary the elevation. Table 93-3 in Chapter 93, Exercise Electrocardiography (Stress) Testing, indicates various protocols, and Figure 93-15 graphically compares METs per minute and VO<sub>2max</sub> as measured for four protocols.

Prepare the patient for the ECG machine to be used in the test.
Locate sites on the chest for electrodes, which are the same locations as for the office ECG (see Chapter 89, Office Electrocardiograms), except that the arm electrodes are placed in the infraclavicular fossae (midclavicle) and the leg electrodes are placed on the lower abdomen just above the beltline (see Fig.

- 93-14). The location of the lateral leads may need to be adjusted to allow application of the transducer to sites for the parasternal and apical windows.
- Prepare the patient for the echo after exercise or dobutamine infusion. The patient should know that it is very important to obtain the recovery images within the first minute, so it will be very important to move in a safely and timely manner to the echo examination table. The patient will then need to lie fairly still in the supine position position until the images are obtained.

# **TECHNIQUE**

# **Getting Started and Resting Echo**

- Review the patient's interval medical history and examine the patient. Based on the history and re-examination, make sure that no contraindication has developed since the last time the patient was seen. Again, determine that in this particular clinicial scenario stress echo is the preferred technique for testing.
- 2. With the patient lying down, obtain and record the resting heart rate, BP, and electrocardiograph.
- 3. Using the left parasternal and apical windows, obtain the supine, resting 2D echo images. A screening assessment should be made of ventricular function, chamber sizes, wall motion thicknesses, aortic root, and valves, unless this assessment has already been performed.
- 4. Perform the exercise or pharmacologic stress test (see Chapter 93, Exercise Electrocardiography [Stress] Testing, about performing and monitoring the standard EET).

# **Exercise Treadmill Echocardiography**

- With the patient standing beside the treadmill, an electrocardiograph should be obtained. At this point, most equipment records data to provide the signal-averaged ECG for future monitoring.
- 6. Begin the exercise treadmill test using the preselected protocol.
- 7. Monitor the patient's symptoms, overall condition, pulse rate, and ECG at all times. Instruct the patient to give adequate warning if the test needs to be stopped. With the exception of submaximal testing, encourage the patient to go as far and as long as possible.
- 8. Record a 12-lead electrocardiograph at the end of each stage, at any time when an abnormality is noted on the monitor, immediately on stopping, and every minute for 8 minutes after exercise during recovery.
- 9. During each stage, at the start of the final minute, ask the patient if there is any chest discomfort, what point he or she has reached on the PES, and whether he or she wants to continue into the next stage. Also record the BP and heart rate near the end of each stage or at the time of any problems.

NOTE: For most patients, their perceived exertion (see Box 93-1 in Chapter 93, Exercise Electrocardiography [Stress] Testing) is reproducible at a given level of exercise and correlates fairly well with their heart rates. Ask patients to indicate on a scale of 0 to 10 how hard they feel they are working with each stage. On the average, most patients feel they increase by 2 to 3 on the exertion scale with each stage in the early part of the study. PES usually increases more rapidly, from 7 to 9, near the end of the study. Rarely will anyone declare a 10. Use of the PES will not only help the clinician plan for gathering data during the stress echo, but it may also help with giving an exercise prescription (see Chapter 93, Exercise Electrocardiography [Stress] Testing, for additional information about giving a customized exercise prescription).

10. After completion of the exercise treadmill test, immediately ask the patient to lie down. Be aware that this step may be uncomfortable for certain patients, especially if they are overweight or having slight difficulty breathing; reassure them that they will not be required to lie down for long. Obtain the needed images within 1 minute and then record the BP and heart rate. If an assistant is available, it is best to be obtaining the vital signs at the same time as the images.

# **Exercise Bicycle Ergometer Echocardiography**

- 5. With the patient sitting on the bicycle, an electrocardiograph should be obtained. At this point, most equipment records data to provide the signal-averaged ECG for future monitoring. There may be value in again explaining to the patient the importance of moving safely and rapidly to the echo examination table immediately after the exercise has stopped in order to obtain the images.
- 6. Begin the exercise test using the preselected protocol. The usual bicycle protocol starts at 25 W of resistance and increases by 25 W every 2 minutes. (A higher initial workload may be appropriate for younger patients or those with a higher estimated exercise capacity.) If images are to be obtained during exercise, many clinicians obtain them at a workload of 25 W and again at peak exercise.
- 7. Monitor the patient's symptoms, overall condition, pulse rate, and ECG at all times. *Instruct the patient to give adequate warning if the test needs to be stopped*. With the exception of submaximal testing, encourage the patient to go as far and as long as possible.
- 8. Record a 12-lead ECG at the end of each stage, at any time an abnormality is noted on the monitor, immediately on stopping, and every minute for 8 minutes after exercise during recovery.
- 9. During each stage, at the start of the final minute, ask the patient if there is any chest discomfort, what point he or she has reached on the PES, and whether he or she wants to continue into the next stage. Also record the BP and heart rate near the end of each stage or at the time of any problems.
- 10. After completion of the upright-bicycle exercise test, immediately ask the patient to lie down. Be aware that this step may be uncomfortable for certain patients, especially if they are overweight or having slight difficulty breathing; reassure them that they will not be required to lie down for long. Obtain the needed images within 1 minute and then record the BP and heart rate. If an assistant is available, it is best to be obtaining the vital signs at the same time as the images.

# **Dobutamine Stress Echocardiography**

**AUTHOR'S NOTE:** Vasodilator infusion (e.g., adenosine, dipyridamole, regadenoson) can be used in a similar manner for perfusion imaging using contrast stress echo.

- 5. The patient can remain in the supine position for dobutamine infusion. Begin the dobutamine infusion following the standard or low-dose protocols. Dobutamine can be initiated at the standard rate of 5 μg/kg/min and increased in 3-minute intervals to 10, 20, 30, and 40 μg/kg/min. (For those with moderate to severely depressed left ventricular function, multivessel disease, or at high risk for an arrhythmia, a low-dose protocol can be used with the infusion initiated at 2.5 μg/kg/min and increased more gradually to 5, 7.5, 10, and 20 μg/kg/min.) At the Mayo Clinic, echo images are also attained at lower doses (5 to 10 μg/kg/min), prepeak, and at peak dose (or after administration of atropine).
- 6. Vigilant monitoring is indicated with the use of dobutamine, especially in patients with moderately to severely depressed left ventricular function or multivessel disease because of the high risk for an arrhythmia. Monitor the patient's symptoms, overall condition, pulse rate, and ECG at all times. Record a 12-lead electrocardiograph at any time an abnormality is noted on the monitor.
- 7. The test is terminated if the target heart rate is achieved (85% of predicted MHR; predicted MHR = 220 age) or with the

appearance of new or worsening wall-motion abnormalities of moderate degree, significant arrhythmias, hypotension, severe hypertension, or intolerable symptoms. If the test is being done for assessment of viability (low-dose protocol), it should be terminated if there is no functional improvement in segments that are akinetic at baseline. Likewise, worsening of function in hypokinetic segments should trigger termination of the test. Conversely, if there is improvement in function using the low-dose protocol and no untoward side effects, the dose can be escalated to match the high-dose protocol (up to  $40~\mu g/kg/min$ ).

8. If the target heart rate is not readily achieved, atropine can be given IV in divided doses of 0.25 to 0.5 mg to a total of 2 mg. The minimum dose of atropine needed to obtain the target heart rate should be used to minimize the risk of the rare complication of central nervous system toxicity. Use of atropine increases the sensitivity of the test in patients taking  $\beta$ -blockers or those with single-vessel CAD.

AUTHOR'S NOTE: Patients given atropine at the 30  $\mu$ g/kg/min dobutamine infusion stage reach target heart rate more quickly and with fewer side effects.

9. Obtain the needed images and then record the BP and heart rate. If an assistant is available, it is best to be obtaining the vital signs at the same time as the images. For persistent symptoms, tachycardia, or severe tachycardia, short-acting IV  $\beta$ -blockers (e.g., metoprolol, esmolol) are effective at reversing the dobutamine effects.

# After Exercise or Pharmacologic Stress Testing

- 1. Immediately after exercise or pharmacologic testing, the patient can be placed in the left lateral recumbent position. Obtain the apical four-chamber images, then the two-chamber images, and finally the parasternal long-axis followed by short-axis images (some laboratories obtain the parasternal images first). Observe recovery of ischemic wall motion abnormalities (usually 3 to 5 minutes after exercise).
- 2. Monitor the BP, heart rate, any symptoms, and the ECG tracing during recovery. Observe the patient in recovery until symptoms, echo, or ECG changes have resolved completely (or for at least 8 minutes if symptoms, echo, or ECG changes resolve earlier).

# **Test Termination Criteria**

A good rule of thumb for stopping the study is *after* the necessary information is obtained and *before* there is a complication. In young or fit individuals, when they reach their predicted maximal heart rate (again, predicted MHR = 220 – age), it may be prudent to explain that all the necessary information has been obtained; however, they may continue to exercise for as long as they desire. (Allowing the patient to make this choice is also indirectly obtaining informed consent.) In older, less fit, or more debilitated patients, those with multivessel disease, and those with a positive test, obtaining at least 85% of predicted MHR is usually adequate for a stress echo. The benefit of going beyond predicted MHR is the ability to give patients a customized exercise prescription based upon their true MHR.

**NOTE:** In the past, authorities denoted two possible definitions of a maximal stress exercise test: (1) achieving a target heart rate greater than 85% of the predicted MHR for that patient's age (i.e., roughly 85% of [220 – age]) or (2) exercise to the point of symptoms. Most authorities now encourage patients to exercise to the point of symptoms (usually generalized or voluntary fatigue or the usual amount of chest pain).

Predicted MHR is not patient specific and is frequently inaccurate. Proceeding to the point of symptoms is contraindicated only for debilitated or elderly patients or if a submaximal test is indicated.

Maximal effort is usually indicated by maximal perceived exertion and the inability to continue at that workload. Also, for stress echo, a rate pressure product (RPP = systolic blood pressure  $\times$  heart rate) greater than 20,000 indicates to the clinician that the patient has given a good effort.

Indications to terminate a study include the following:

- Significant elevated BP (systolic blood pressure >250 mm Hg, diastolic blood pressure >115 mm Hg) occurs.
- Significant heart rate abnormalities (inability to obtain 120 beats per minute [bpm] or excessive high heart rate for level of exertion) appear.
- Systolic blood pressure drops more than 20 mm Hg below resting value, especially after the first minute or two of the study (most dangerous if it reflects LV dysfunction; in that situation there is a high risk of life-threatening arrhythmias).
- Anginal chest pain worsens (severe enough that the patient desires to stop); it is not prudent for patients to exercise beyond the point at which they obtain their "usual" amount of chest discomfort. In other words, there is no reason for the patient to demonstrate his or her worst chest pain while performing the study.
- Central nervous system symptoms (e.g., dizziness, disorientation) appear.
- Signs of poor perfusion (e.g., cyanosis, pallor) or severe ventricular dysfunction (e.g., dyspnea) occur. Remember that in the elderly, stability can deteriorate very rapidly; poor perfusion may be indicated solely by a loss of color in an elderly patient.
- Serious arrhythmias develop.
- Target heart rate has been attained.
- Patient wants to stop the test (especially elderly patients, in whom there may be little warning of a complication about to happen).
- Technical problems with equipment (e.g., ECG monitor, systolic blood pressure monitoring) occur.

#### INTERPRETATION

Chapter 93, Exercise Electrocardiography (Stress) Testing, discusses interpretation of the EET. ECG criteria are used to determine whether the EET is positive or negative. The test result can also be abnormal because of other responses (e.g., BP, symptoms). Rather than just labeling the result as normal, positive, or abnormal, the specific responses to exercise should be identified and documented. It should be noted that occasionally the EET is falsely positive or falsely negative; if the echo images are good, the results of the stress echo take precedence over the EET results.

# Normal Echocardiographic Responses to Exercise

- Myocardial segments visualized have normal contraction at rest and become hyperdynamic with exercise or infusion of dobutamine.
- A normal stress echo is defined as normal left ventricular wall motion at rest and with stress.
- Ejection fraction normally increases with exercise.
- Left ventricular end-systolic volume normally decreases with exercise.

# Abnormal Echocardiographic Responses to Exercise

- Cardiac segment changes from normal to hypokinetic, from hypokinetic to akinetic, and from akinetic to dyskinetic are considered wall motion abnormalities.
- Resting wall motion abnormalities, unchanged with stress, are classified as "fixed" and most often represent regions of prior

TABLE 94-2 Typical Rest and Stress Wall  Motion Responses							
Rest	Stress	Interpretation					
Normal Normal Akinetic Hypokinetic Hypokinetic/akinetic	Hyperkinetic Hypokinetic/akinetic Akinetic Akinetic/dyskinetic Normal	Normal Ischemic Prior infarction Ischemic or prior infarction Viable					

infarction. Fixed wall motion abnormalities that develop new or worsening wall motion abnormalities are indicative of ischemia.

- Typical patterns are seen with normal, ischemic, and prior infarction responses to stress echo (Table 94-2).
- Function in each segment is graded at rest and with stress as normal or hyperdynamic, hypokinetic, akinetic, dyskinetic, or aneurismal. Table 94-3 provides a scoring system).
- Images from low or intermediate stages of supine bicycle or dobutamine infusion should be compared with peak stress images to maximize the sensitivity for detection of CAD.
- Stress-induced changes in left ventricular shape, increase in cavity size, and lack of increase in global contractility indicate ischemia.
- Ischemia also delays the onset of contraction and relaxation and decreases the maximum amplitude of contraction.

# **Segmental Wall Motion Analysis**

- One expert (Ellestad) feels the standard four-chamber view provides the most information.
- The American Society of Echocardiography (ASE) suggests that either a 16- or 17-segment model of the left ventricle (see Fig. 90-20 in Chapter 90, Echocardiography) be used for segmental wall motion analysis. The extra segment in the 17-segment model is the "apical cap," which is the portion of the left ventricle located below where the ventricular cavity is seen.
- Although there is some variability among data reported when segmental wall analysis is used to evaluate stress echo results (i.e., thresholds from calculated sum ratios of wall motion abnormalities used to define patients at high risk have been variable), the authors still use Figure 94-1 to quantify the results. Each segment is evaluated and scored at rest and during stress (bicycle or pharmacologic) or after stress (treadmill). The sum of all the segments from the stress echo is divided by the sum of the resting segments. Patients considered high risk have a score greater than 1.4.

# Ejection Fraction and End-Systolic Volume Analysis

The ejection fraction should increase on the postexercise echo images and the end-systolic volumes decrease (with the exception of recumbent bicycle protocol). On these images, no change in the

TABLE 94-3 Wall Motion Scoring	
Description	Score
Hyperkinetic (hyperdynamic) Normal Mildly hypokinetic* Hypokinetic Severely hypokinetic* Akinetic Dyskinetic Aneurysm	0 1.5 2 2.5 3 4 5

<sup>\*</sup>Optional scores used by some clinicians.

ejection fraction or end-systolic volume, a decrease in the ejection fraction, and an increase in the end-systolic volume are all indicative of CAD and increased patient risk of a cardiovascular event.

#### **Other Parameters Followed**

- Heart rate. Failure to obtain a heart rate of 120 bpm is chronotropic incompetence with a resultant poor prognosis (approximately 15% per year will experience a coronary event); it may also indicate early sick sinus syndrome or multivessel CAD (often small-vessel CAD).
- Heart rate recovery. Failure of the heart rate to decrease 12 bpm in the first minute of recovery is an abnormal heart rate recovery. This indicates a two- to fourfold increased risk of death over the next 5 years.
- Blood pressure. If the systolic BP drops below resting, it predicts
  either a poor prognosis or severe CAD. In one study, men with
  a maximal exercise systolic blood pressure below 140 mm Hg had
  a 15-fold increase in the annual rate of sudden death when compared to those whose BPs exceeded 200 mm Hg.

#### **False-Positive Results**

Box 94-2 lists causes of false-positive results on stress echocardiography. Advanced age, marked hypertension, a cardiomyopathy, or taking a  $\beta$ -blocker can blunt the normal hypercontractile response to exercise.

# **False-Negative Results**

Box 94-2 also lists causes of false-negative results on stress echocardiography. Suboptimal stress is a primary cause of false-negative tests. An adequate level of stress is frequently defined as achievement of 85% or more of the patient's age-predicted maximal heart rate for exercise or dobutamine stress or a rate pressure product of 20,000 or more for exercise testing.

#### **DETERMINING PROGNOSIS**

## **Normal Stress Echocardiogram**

A negative stress echo is very reassuring because prognosis is excellent. Patients have less than 1% annual risk of MI or cardiac events, which is equivalent to that of an age- and sex-matched population (Box 94-3). These patients do not require further diagnostic evaluation unless there is a change in signs or symptoms. Patients with a negative pharmacologic stress echo have a slightly higher risk of cardiovascular events, perhaps due to their inability to exercise, other comorbidities, or typically older age at the time of testing. However, a negative pharmacologic stress echo still implies less than 2% annual risk of MI or cardiac death (see Box 94-3).

# Uninterpretable or Incomplete Exercise Test Results

This result is caused by failure to attain at least 85% of the age-predicted MHR, with absence of ischemic changes in a well-motivated patient ( $\beta$ -blockers are a common cause of this).

#### **Positive and Abnormal Studies**

In addition to segmental wall analysis and evaluation of the ejection fraction/end-systolic volumes, other factors are known to affect risk (Box 94-4). While the degree that each of these factors affects risk is variable, we know that the more factors a patient possesses, the higher the risk. Certain investigators also attempt to combine the results of the EET to estimate risk using the Duke Treadmill Nomogram (see Fig. 93-18 in Chapter 93, Exercise

# Box 94-2. Causes of False-Positive and False-Negative Results on Stress Echocardiography

#### Causes of False-Positive Results

Hypoxemia or anemia—can cause ischemia unrelated to CAD

Apical hypokinesis due to LVH—can cause wall motion abnormalities

Hypertension (poorly controlled)—can cause ischemia or wall motion abnormalities

Cardiomyopathy—idiopathic cardiomyopathy can cause ischemia; other cardiomyopathies can cause wall motion abnormalities

Long-standing hypertension—can cause wall motion abnormalities, even without resting left ventricular function and in absence of LVH

Mitral valve prolapse syndrome and valvular heart disease Coronary spasm (Prinzmetal's or variant angina)

Mitral valve replacement or annulus calcification can lead to decreased motion of the basal inferior and basal inferoseptal segments due to tethering

Left bundle branch block, right ventricular pacing, and previous open heart surgery can lead to decreased septal wall motion (abnormal septal motion usually present at rest)

Inadequate recording equipment, incorrect criteria, improper interpretation, or improper transducer placement

Technical or observer error

Advanced age

β-blocker therapy

#### Causes of False-Negative Results

Failure to achieve an adequate workload (heart rate >85% of age-predicted MHR for exercise or pharmacologic stress, or rate pressure product of at least 20,000 for exercise echo)

Single vessel, especially left circumflex, CAD (supine bicycle testing has higher sensitivity)

Concentric remodeling or LVH (especially for dobutamine stress, because affected patients have increased relative wall thickness and smaller left ventricular cavity volume)

Significant aortic or mitral valve regurgitation (due to resulting hyperdynamic state)

Failure to use other information (e.g., EET results, systolic blood pressure drop, symptoms, dysrhythmia, heart rate response) in test interpretation

Inadequate recording equipment, incorrect criteria, improper interpretation, or improper transducer placement

Technical or observer error

CAD, coronary artery disease; EET, exercise electrocardiography testing; LVH, left ventricular hypertrophy; MHR, maximal heart rate.

Electrocardiography [Stress] Testing). This nomogram is most accurate for those patients with a positive study and able to achieve 5 METs, a heart rate of 120 bpm, and an RPP of more than 25,000. Box 94-3 is utilized for further quantifying those patients considered high risk (greater than fourfold increased risk over the low-risk group previously defined).

# **Viability Studies**

The highest sensitivity of the dobutamine test for viability is noted when there is improvement in wall motion with the low-dose

# Box 94-3. Stress Echocardiography Predictors of Risk

#### Low Risk

<1% per year risk of MI or cardiac events: Normal exercise echo and good exercise capacity (≥7 METs in men, 5 METs in women)

<2% per year risk of MI or cardiac death: Normal pharmacologic stress echo (defined as HR > 85% of age-predicted MHR for dobutamine stress echo and low to intermediate pretest probability\*)

#### High Risk

Extensive resting wall motion abnormalities (four to five segments)

Baseline ejection fraction <40%

Extensive ischemia (four to five segments)

Multivessel ischemia

Resting wall motion abnormalities and remote ischemia Low ischemic threshold

Ischemia with 20 µg/kg/min dobutamine

Ischemic wall motion abnormalities, no change or decrease in ejection fraction

HR, heart rate; MHR, maximum heart rate; MI myocardial infarction.

\*See Determination of Pretest Probability in Indications section in this chapter.

†Greater than fourfold increase over low risk.

From American Society of Echocardiography Recommendations for Performance, Interpretation and Application of Stress Echocardiography. J Am Soc Echocardiogr 20:1021–1041, 2007.

# Box 94-4. Factors Increasing Risk in Patients with Normal Stress Echocardiography Results\*

Increasing age

Male sex

Diabetes

High pretest probability<sup>†</sup>

History of dyspnea or CHF

History of MI

Limited exercise capacity

Inability to exercise

EET demonstrates ischemia

Resting wall motion abnormalities

IVH

Ischemia on stress echo

Baseline reduced ejection fraction

No change or increase in end-systolic volume with exercise No change or decrease in ejection fraction with exercise Increasing wall motion score with stress

CHF, congestive heart failure; EET, exercise electrocardiography testing; LVH, left ventricular hypertrophy; MI, myocardial infarction.

\*The degree to which each factor increases risk is variable. †See Determination of Pretest Probability in Indications section of this chapter (>90% by calculations in that section).

From American Society of Echocardiography Recommendations for Performance, Interpretation and Application of Stress Echocardiography. J Am Soc Echocardiogr 20:1021–1041, 2007.

protocol. Viability is defined by improvement by at least one grade in two or more wall segments (see Table 94-3). Patients with a large area of viable myocardium (>25% of left ventricle) have a greater chance of improving ejection fraction and a better outcome (decreased remodeling, persistent improvement in heart failure, lower incident of cardiac events) when revascularized.

#### **COMPLICATIONS**

- Hypotension
- Congestive heart failure exacerbation
- Severe cardiac arrhythmia
- Cardiac arrest
- Acute MI
- Acute central nervous system (CNS) event, such as syncope or stroke
- Death

#### POSTPROCEDURE PATIENT EDUCATION

Patients should be counseled appropriately regarding their risk and whether consultation with a cardiologist is indicated. Patients should be informed that stress echocardiography, just like any other noninvasive study for diagnosing CAD, is not 100% accurate. However, it usually diagnoses those coronary arteries with greater than 70% obstruction. Medical management is probably best for those vessels with less than 70% obstructions and the patient should probably be reassured that this is already ongoing (i.e., management of diabetes, hypertension, lipids). Regardless, individuals with a future change in symptoms or symptoms suggestive of coronary ischemia such as chest discomfort, palpitations, or shortness of breath with exertion should be evaluated by their clinician regardless of the result of the stress echocardiogram.

In patients with CAD or a high probability of CAD, counseling should be directed at modifying risk factors and medical management. Exercise prescriptions should be given and discussed. See Chapter 93, Exercise Electrocardiography (Stress) Testing, for how to give an aerobic exercise prescription if not contraindicated. A cardiac rehabilitation program should be considered.

### **CPT/BILLING CODES**

- 93016 Cardiovascular stress testing using maximal or submaximal treadmill or bicycle exercise, continuous ECG monitoring, and pharmacologic stress; physician supervision only, without interpretation and report
- 93017 Tracing only, without interpretation and report
- 93018 Interpretation and report only
- 93350 Echocardiography, transthoracic, real-time with image documentation (2D), with or without M-mode recording, during rest and cardiovascular stress test using treadmill, bicycle exercise, and pharmacologically induced stress, with interpretation and report (Stress testing codes 93016 to 93018 should be reported, when appropriate, in conjunction with 93350 to capture the cardiovascular stress portion of the study. Do not report 93015 in conjunction with 93350.)
- 93351 Including performance of continuous electrocardiographic monitoring, with physician supervision (Do not report 93351 in conjunction with 93015 to 93018, 93350.)

# **ICD-9-CM DIAGNOSTIC CODES**

- 394.0 Mitral stenosis, rheumatic
- 394.2 Mitral stenosis with insufficiency, rheumatic
- 402.10 Hypertensive heart disease or hypertensive LVH, benign, without congestive heart failure (CHF)
- 402.11 Hypertensive heart disease, benign, with CHF

- 410.00 Acute MI, of the anterolateral wall, episode of care unspecified
- 410.20 Acute MI, of the inferolateral wall, episode of care unspecified
- 410.90 MI, acute, unspecified site and episode
- 412 Old MI (healed or no symptoms)
- 413.9 Other and unspecified angina pectoris
- 414.00 Coronary atherosclerosis, of unspecified type of vessel, native or graft
- 414.01 Coronary atherosclerosis, of native coronary artery
- 414.02 Coronary atherosclerosis, of autologous vein bypass graft
- 414.04 Coronary atherosclerosis, of artery bypass graft
- 414.05 Coronary atherosclerosis, of unspecified type of bypass
- 414.8 Chronic coronary insufficiency or ischemic heart disease
- 414.9 Chronic ischemic heart disease, unspecified

- 416.0 Pulmonary hypertension, primary, chronic
- 416.8 Pulmonary hypertension, secondary, chronic
- 420.90 Pericardial effusion, acute
- 420.91 Pericarditis, acute, idiopathic
- 422.90 Myocarditis, acute
- 423.9 Pericardial effusion, unspecified disease of pericardium
- 424.0 Mitral valve disorders, nonrheumatic (incompetence, insufficiency, regurgitation, prolapse)
- 424.1 Aortic valve disorders (incompetence, insufficiency, regurgitation, stenosis)
- 425.4 Cardiomyopathy, congestive, constrictive, familial, hypertrophic, idiopathic, restrictive, obstructive, nonobstructive, NOS)
- 425.5 Cardiomyopathy, alcoholic
- 426.3 Left bundle branch block, complete or NOS
- 426.4 Right bundle branch block
- 427.5 Cardiac arrest
- 427.31 Atrial fibrillation
- 427.69 Ventricular premature beats, contractions, or systoles
- 428.0 Congestive heart failure
- 428.1 Congestive heart failure, left, acute
- 428.4 Combined systolic and diastolic heart failure
- 428.21 Systolic heart failure, acute
- 428.22 Systolic heart failure, chronic
- 428.31 Diastolic heart failure, acute
- 429.1 Cardiomyopathy, arteriosclerotic
- 429.3 Cardiomegaly or cardiac dilation or hypertrophy
- 429.79 Mural thrombus (atrial, ventricular) acquired following myocardial infarction
- 441.01 Aortic dissection, thoracic
- 785.1 Palpitations
- 786.50 Chest pain, unspecified
- 786.51 Precordial pain

#### **SUPPLIERS**

(For full contact information go to www.expertconsult.com.)

For stress testing equipment, see the Suppliers section in Chapter 93, Exercise Electrocardiography [Stress] Testing. Most manufacturers on that list also sell defibrillators. Purchasing these as part of a package is often cost effective. For echo equipment, there are several manufacturers with products ranging from the very basic to the very sophisticated. Small hand-held machines are now available. Acuson Siemens, Biosound Esaote, General Electric Healthcare, Medison, Phillips, and Toshiba all offer a range of devices from hand-held to research oriented (see the Suppliers section in Chapter 172, Obstetric Ultrasonography, and the Suppliers listings in Appendix D for the Internet and mailing addresses and the phone numbers for many manufacturers). An excellent way to review the equipment is to visit the company websites. Used equipment is also available, but the cost

and inconvenience of service and repairs are often a disadvantage. To avoid large capital equipment costs, service companies will bring portable echocardiography equipment to the physician's office for this procedure and split the fees. Over-reading services are also available. The following are two companies with which the authors are familiar:

### Echocardiography equipment

General Electric Healthcare Toshiba America Medical Systems Emergency/ACLS medication kits Banyan International Corp.

# **THORACENTESIS**

Terry S. Ruhl • Jennifer L. Good

Pleural effusions are common in primary care. Sampling the fluid may yield information important for treatment decisions or may help the patient feel better. Similar techniques can also be used to treat certain pneumothoraces.

### **ANATOMY**

The pleural "space" is a potential space between the visceral pleura, which is adherent to the lung, and the parietal pleura, which is adherent to the chest wall. Normally, it contains only a thin film of lubricating fluid. When this space becomes filled with air or extra fluid, it may become painful or increase the work of breathing.

#### **INDICATIONS**

- Any significant (>10 mm on lateral decubitus radiograph) pleural
  effusion of unknown etiology (effusions with an easily explained
  cause, such as congestive heart failure, may be observed for
  response to therapy)
- Large symptomatic effusion
- Spontaneous pneumothorax (a minimally symptomatic, spontaneous pneumothorax of less than 20% may be merely observed if the patient has no significant underlying lung disease)

# **CONTRAINDICATIONS**

# **Absolute**

- Patient refuses the procedure
- When chest tube placement is planned and would be more appropriate
  - Known or suspected hemothorax
  - Empyema or complicated parapneumonic effusion
  - Large spontaneous pneumothorax
  - Spontaneous pneumothorax in a patient with underlying lung disease

# **Relative**

- Coagulopathy or patient undergoing anticoagulant therapy (international normalized ratio >1.5, consider reversing the coagulopathy or anticoagulant before performing thoracentesis).
- Thrombocytopenia (platelet count <50,000).
- Inability to cooperate or sign informed consent.
- Very small pleural effusions (<10 mm thick on lateral decubitus chest radiograph), unless aided by real-time ultrasonography.
- Local skin compromise (e.g., cellulitis, burn, pyoderma, herpes zoster infection).
- Unstable medical condition.
- Positive-pressure ventilation (though one study has found thoracentesis to be as safe in ventilator-dependent patients as in patients not being mechanically ventilated).

- Radiographic evidence of loculated pleural effusions making localization of fluid uncertain unless aided by real-time ultrasonography.
- Patients with chronic obstructive pulmonary disease are at increased risk for complications.

### **EQUIPMENT AND SUPPLIES**

Commercial thoracentesis trays are available. If a commercial tray is used, the manufacturer's instructions *must* be reviewed because equipment varies. Alternatively, the equipment described in the following sections can be assembled.

# **Preparation and Anesthesia**

- Povidone-iodine solution or chlorhexidine and applicators
- Fenestrated drape or sterile towels
- 10-mL Luer-Lok syringe
- 25-gauge or smaller needle
- 1½- to 2-inch, 22-gauge needle
- Lidocaine 1% to 2% with epinephrine

#### Insertion

- Sterile gloves
- 50-mL Luer-Lok syringe, three-way stopcock
- 2½-inch, 18-gauge needle (for air), 2½-inch, 15-gauge needle (for fluid), or 16-gauge catheter over needle (can decrease risk of pneumothorax, but kinks can increase the "dry tap" rate).

NOTE: Obese people may require longer needles.

 Specimen tubes: one red top, one lavender top, culture tubes (aerobic and anaerobic), 10- to 50-mL red top for cytology, possibly 1 green top, ice for pH

#### **Optional**

- Sterile plastic tubing
- Curved clamp for marking insertion depth on needle
- 500- or 1000-mL vacuum bottles
- Telemetry, oximetry, blood pressure monitoring, and supplemental oxygen

# **Dressing**

Use sterile gauze pads and adhesive tape or adhesive bandage with antibiotic ointment.

#### **PRECAUTIONS**

The use of real-time ultrasonographic guidance is helpful in situations where there is a small effusion (<10 mm free-flowing pleural fluid on lateral decubitus radiograph), there is presence of a loculated pleural effusion, the patient is receiving positive-pressure

mechanical ventilation, or in other high-risk situations. "Marking" the location for later drainage is unhelpful because fluid shifts, but marking at the time of aspiration may be helpful. Use of ultrasonography may also help determine needle depth and the angle at which the needle should be directed. Removal of large amounts of fluid may increase the incidence of postprocedure complications, although many advocate "draining it dry."

#### **TECHNIQUE**

# **Patient Positioning and Insertion Site**

- 1. Seat the patient comfortably (Fig. 95-1) with arms supported on a table. The lower back should be kept as vertical as possible so that the most dependent portion of the hemithorax is posterior, thereby keeping free-flowing fluid in a posterior location.
  - **NOTE:** Debilitated patients can be placed in the lateral decubitus position, lying on the side of the effusion with their back near the edge of the bed. The procedure would then be performed in the mid-scapular line or the posterior axillary line.
- Confirm the location and extent of fluid or air by percussion, auscultation, and study of posteroanterior, lateral, and lateral decubitus (fluid-affected side down) chest radiographs.
  - **NOTE:** If available, ultrasonography may be very helpful for completing this step (see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]).
- 3. Select the needle insertion site. Use an area one or two interspaces below the fluid level and 5 to 10 cm lateral to the spine. Do not insert below the eighth intercostal space.
- 4. Mark insertion site with marker or by applying pressure from the hub of a needle or pen.
- Verify the patient's identity, ensure the insertion site is correctly marked, and take a "time out" to verify this with everyone present.

# Preparation and Anesthesia

 Prepare the skin with povidone—iodine or chlorhexidine. Use sterile technique and universal blood and body fluid precautions. Drape with sterile towels or fenestrated drape. Some experts monitor all patients with telemetry, oximetry, and automatic blood pressure equipment and have supplemental oxygen available during this procedure, especially if the patient has underlying pulmonary disease.

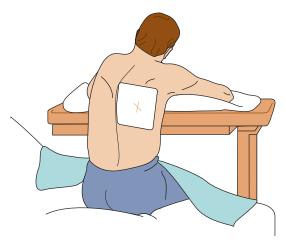

Figure 95-1 Position for fluid removal.

- 2. Raise a skin wheal using lidocaine with epinephrine and a 25-gauge or smaller needle attached to a 10-mL syringe.
- 3. Angle a ½-inch 22-gauge needle slightly downward, and insert it through the skin wheal so that the needle tip touches the superior border of a rib, aspirating and injecting as you advance. "Walk" the needle over the superior margin of the rib and deeper into the interspace, anesthetizing the intercostal muscle layers (Fig. 95-2A).
- 4. To confirm the presence of fluid or air with the small anesthesia needle, continue advancing the needle while aspirating and injecting until the parietal pleura has been penetrated. (A "pop" may be felt, or fluid/air aspirated.) Warn the patient that there may be a twinge of pain as you go through the pleura. Inject more lidocaine. Note the depth. Consider placing a clamp on the needle at the skin level to mark the depth (Fig. 95-2B). Withdraw the needle. If no fluid is obtained, ultrasonographic guidance is recommended. If air is unexpectedly obtained, try a lower intercostal space.

# Aspiration Option I (If No Kit Available): Needle-Only Insertion Technique

- Prepare the equipment. Attach a 15-gauge needle to a 50-mL syringe with a three-way stopcock. Mark the previously measured depth on this needle with a clamp. Test the equipment to be sure you are well acquainted with the use of the stopcock. Open the stopcock to the syringe.
- Insert the thoracentesis needle in the same track as the anesthesia needle, and advance it to the level of the clamp. ("Walk" over the rib, not under it, to avoid damaging vessels and nerves). Aspirate to confirm placement. Keep the clamp attached to prevent penetrating too deeply.

# Aspiration Option 2: Catheter-over-Needle Insertion Technique

(Use a commercially prepared thoracentesis tray. Read the manufacturer's instructions carefully.)

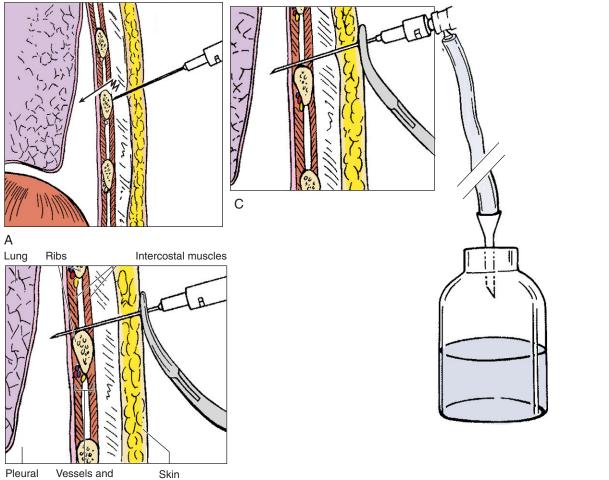

- 1. Prepare the equipment. Familiarize yourself with the stopcock. Visualize the measured insertion depth on the needle.
- 2. Insert the thoracentesis needle in the same track as the anesthesia needle, aspirating with the syringe until fluid is obtained.
- 3. Making sure the stopcock is turned off to the environment, completely withdraw the needle, leaving the catheter in the pleural space. As the needle is removed, quickly turn the stopcock to close the catheter to the environment. Alternatively, a gloved finger can be used to quickly cover the catheter hub after the needle is removed to prevent air from entering the pleural cavity.

### **Completing the Procedure**

1. For stopcock and evacuated container: Attach one end of the tube to the stopcock and the other end to a second 15-gauge needle. Insert the needle through the seal of an evacuated container, and open the stopcock to the evacuated container (Fig. 95-2C).

For stopcock and open container: Pull the fluid into the syringe. Turn the stopcock off to the needle, being careful not to open the needle to the environment. Push the fluid out of the syringe into the container. Alternate aspiration into the syringe and emptying into the container.

- 2. After withdrawal of the necessary amount of fluid, remove the needle while the patient is exhaling.
- 3. Dress the site with an occlusive, sterile dressing.
- Send the fluid for analysis (see "Interpretation of Results" for details). In most cases, a volume of 50 to 60 mL is sufficient for diagnostic tests.

**Figure 95-2 A,** Anesthetizing the intercostal muscle layers. Needle is "walked" over the rib. **B,** Clamp is placed to mark the depth to the effusion. **C,** Needle in pleural space with fluid draining into evacuated bottle.

Consider an end-expiratory chest radiograph to check for a pneumothorax. Some experts repeat this radiograph in 4 to 6 hours to look for delayed pneumothorax.

# Thoracentesis for Aspiration of a Simple Spontaneous Pneumothorax

space

В

nerves

- 1. Position the patient supine with the head of the bed elevated at a 30- to 45-degree angle and infiltrate local anesthetic into the second or third intercostal space in the mid-clavicular line (Fig. 95-3). (Alternatively, the patient can be placed in the lateral decubitus position and the fourth or fifth intercostal space in the mid-clavicular line can be used.)
- 2. Using a catheter over a needle (at least 16 Fr and 2 inches long), enter the pleural space and withdraw the needle. As described earlier, "walk" the needle over the cephalic surface of the rib.
- 3. When the pleural space is entered, remove the needle from the catheter during exhalation and attach a three-way stopcock and 60-mL Luer-Lok syringe to the catheter. Be sure to occlude the hub of the catheter during this maneuver to prevent air entry into the pleural space.
- 4. Using the three-way stopcock, manually aspirate air into the 60-mL syringe. Stop when resistance to aspiration is felt, the patient coughs excessively or experiences chest pain or dyspnea, or more than 2 L of air is removed (this suggests the need for a chest tube). Remove the catheter.

5. Obtain a chest radiograph. If the pneumothorax is very small or has resolved, the procedure has been successful. Monitor for another 4 to 6 hours and discharge if a subsequent chest radiograph shows no recurrence of the pneumothorax.

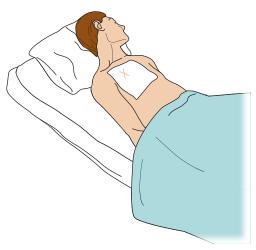

Figure 95-3 Position for air removal.

# **SAMPLE OPERATIVE REPORT**

See a sample operative report online at www.expertconsult.com.

### **COMMON ERRORS**

- Stopcock confusion—mistakenly opening the needle or catheter to the environment
- Missing the effusion—by shifting patient position or not using ultrasonography for small effusions
- Wrong side procedure—may occur if radiographs are malpositioned, mislabeled, or not confirmed by physical examination
- Kit changes—being given an unfamiliar kit without reviewing the instructions

# **COMPLICATIONS**

- Pneumothorax may result if air is introduced through the needle or catheter, or if the visceral pleura is punctured. Between 3% and 20% of procedures produce a pneumothorax, which requires treatment with a chest tube about 20% of the time. Pneumothorax incidence may be reduced with ultrasonographyguided thoracentesis. Insert the needle only as far as needed to obtain fluid. Get comfortable with the equipment, especially the stopcock, before insertion. Use of smaller needles and short bevels, and removal of less fluid, may also decrease the risk of pneumothorax.
- Hemothorax may result from laceration of intercostal vessels or internal mammary vessels, but is rare. To reduce the risk of hemothorax, insert the needle just above the rib, avoiding the neurovascular bundle that runs below each rib. Never puncture medial to the mid-clavicular line.
- The spleen, liver, or diaphragm may be lacerated. To avoid lacerations to these organs, do not insert the needle lower than the eighth intercostal space posteriorly.
- Risk of hypovolemia and reexpansion pulmonary edema can be minimized by removing less than 1.5 L of fluid at a time (although many experts advocate draining the effusion dry). Remove fluid slowly and stop if the patient develops a cough, dyspnea, or chest pain.
- A catheter fragment may be left in the pleural space. To avoid this possibility, never withdraw a catheter over the needle.
- Failure to obtain fluid can occur. For improved success rates, pay close attention to landmarks obtained by auscultation, percussion, and radiographic examination. Consider ultrasonographic guidance.
- Infection can occur. To minimize this possibility, use sterile technique and avoid inserting through infected skin.
- Pain is associated with thoracentesis. Use adequate local anesthesia, especially at the pleura.
- Hypoproteinemia is a possibility. To reduce the risk of this problem, avoid repeated thoracenteses.

### POSTPROCEDURE MANAGEMENT

Because the risk of complications is low, a post-thoracentesis chest radiograph is necessary only if air was obtained during the thoracentesis, or if the patient is mechanically ventilated or develops cough, chest pain, hypoxia, or dyspnea during or after the procedure. If a thoracentesis is performed for the management of a small, primary spontaneous pneumothorax, a chest radiograph should be obtained and the patient should be observed for recurrent pneumothorax for at least 6 hours.

Hypoxemia is very common after thoracentesis and occurs because of ventilation–perfusion mismatching in the newly expanded lung. Oxygenation should be checked periodically by pulse oximetry after thoracentesis and supplemental oxygen provided if necessary.

#### POSTPROCEDURE PATIENT EDUCATION

The dressing should stay on for 24 hours. The patient should inform someone if shortness of breath increases, there is fever, or there is redness at the puncture site.

# INTERPRETATION OF RESULTS

The first important distinction is whether the fluid is a transudate (unbalanced hydrostatic forces) or an exudate ("leaks in the system"). If the lactate dehydrogenase (LDH) levels in the fluid and the pleural fluid/serum ratios for LDH and protein are all normal, the fluid is a transudate and further studies are unlikely to give useful information. Most transudates are from congestive heart failure, with the rest associated with hypoalbuminemia, hepatic hydrothorax, hydronephrosis, pulmonary embolism, peritoneal dialysis, or trapped lung. Occasionally, pleural effusions that appear to be due to congestive heart failure may be classified as an exudate using traditional measures of LDH and total protein, particularly if the patient has been treated with diuretics. In this case, the use of a serum-pleural effusion albumin gradient (SEAG) can be useful. A SEAG of greater than 1.2 g/dL will classify the pleural effusion as transudative, and less than 1.2 g/dL as exudative (Roth and colleagues 1990). One diagnostic approach is to send some of the fluid for protein, pH, LDH measurement, and possibly aerobic and anaerobic culture and sensitivities while storing the remaining fluid for the other tests if the fluid proves to be an exudate (Fig. 95-4). Causes of exudates include cancer, pneumonia, trauma, tuberculosis, pulmonary embolism, pancreatitis, rheumatoid arthritis, and systemic lupus erythematosus. Up to 50% of patients with a pulmonary malignancy will have neoplastic cells in the pleural fluid, so sending exudates for cytology is important. Low pH (<7.2) can indicate a complicated parapneumonic effusion, which may require chest tube drainage. See Table 95-1 for potentially useful tests and their significance.

# ANAL FISSURE AND LATERAL SPHINCTEROTOMY AND ANAL FISTULA

James A. Surrell

#### **ANAL FISSURE**

Anal fissure is defined as a painful linear ulcer (tear) of the distal anal canal, located just inside the anal opening and extending cephalad toward the dentate line (Fig. 96-1). The most common cause of an anal fissure is from passing a large, firm, forced bowel movement. The history of a patient with anal fissure is so characteristic that the diagnosis can usually be made accurately based on the history alone. Patients complain of moderate to severe pain during and after bowel movements and have a variable amount of bleeding. The painful symptoms nearly always resolve within 15 to 30 minutes. Rarely, the patient with an anal fissure complains of severe and constant pain, but this is usually seen only with a severe, deep anal fissure with associated significant anal spasm. A small amount of bleeding with bowel movements is common ("just on the toilet paper"), with frank bleeding rare.

The severe pain, "like glass is cutting me," is thought to be secondary to tearing the fissure open and associated *internal anal sphincter spasm*. Subsequently, avoiding constipation and keeping the bowel movements soft along with relieving the anal muscle spasm is the goal of all therapies.

The *internal* anal sphincter is a totally involuntary muscle and responds to pain by contracting, which leads to more pain and a smaller opening through which the stool must pass, thus creating a vicious cycle. The *external* sphincter generally acts in an involuntary fashion but is under voluntary control. Both sphincters form a ring of muscle around the anus (Fig. 96-2).

The history must include whether the fissure is acute or chronic. *Chronic fissure* can arbitrarily be defined as one that has been present with signs and symptoms of pain or bleeding for more than 3 months. Unless the symptoms are extremely disabling, all fissures should be given a trial of conservative management, as discussed later. If conservative management fails, lateral internal sphincterotomy is the procedure of choice for treatment of an anal fissure.

Once the history suggests an anal fissure, the diagnosis can usually be made easily on visual examination of the external anus and with gentle digital examination. The left lateral decubitus position is recommended for patients undergoing anorectal examination. With gentle eversion of the anoderm, one can usually directly visualize the fissure. Touching the fissure with a cotton-tipped applicator confirms the diagnosis if this reproduces the painful symptoms experienced with bowel movements. If necessary, a digital examination with good lubrication will confirm not only pain but marked increased sphincter tone due to spasm. Finally, if the diagnosis is in doubt, the anoscopic examination can provide more direct visualization. In classic cases, the insertion of the anoscope may be so painful

that it should be deferred. It should be performed at a later time to identify other possible diseases.

Anal fissures occur most commonly in the posterior midline. Approximately 90% of fissures are in this location, and 10% are located in the anterior midline. If the clinician sees an anal fissure in any location other than the anterior or posterior midline, a thorough gastrointestinal work-up is necessary to rule out the presence of inflammatory bowel disease (IBD) or other very rare causes such as tuberculosis, syphilis, occult abscess, leukemic infiltrates, carcinomas, herpes, or acquired immunodeficiency syndrome.

If it is present, IBD with an atypical fissure is most commonly Crohn's disease. Another physical examination feature that should raise the suspicion of perianal Crohn's disease is the presence of fleshy, edematous skin tags (see Chapter 108, Removal of Perianal Skin Tags [External Hemorrhoidal Skin Tags]). If the examiner suspects IBD, upper gastrointestinal with small bowel x-ray films are necessary, as well as colonoscopy or barium enema radiography combined with flexible sigmoidoscopy. Magnetic resonance imaging enterography also may be used to evaluate for Crohn's disease and other bowel lesions.

#### **Treatment**

If the patient has symptoms of moderate to severe pain or bleeding during and after bowel movements, he or she probably has an anal fissure. As noted, the initial goal of therapy is to keep the bowel movements soft and easy to pass while providing pain relief. If these symptoms are severe, disabling, and constant, surgical intervention should be considered sooner rather than later.

However, for most fissures, a 1- to 3-month trial of *conservative management* is indicated. This management includes a *high-fiber diet* of at least 30 g of dietary fiber, six to eight glasses of water, and 3 to 6 g of commercially available fiber supplements per day. If the fissure pain is severe, consider prescribing 5% *lidocaine ointment* to be applied to the fissure on arising and at bedtime, as needed throughout the day, and again after bowel movements. Commercially available nonprescription ointments and creams are minimally effective in the treatment of anal fissures. They may, however, be used to lubricate the anal canal for bowel movements. Steroid preparations may or may not be helpful, but they are not intended for long-term use.

Specifically advise patients not to use any ointment or cream with a rectal tube-tipped applicator or any suppositories because these products and devices tend to worsen the symptoms of an anal fissure. Advise patients to apply a small amount of any recommended ointment or cream directly to the fissure with a finger

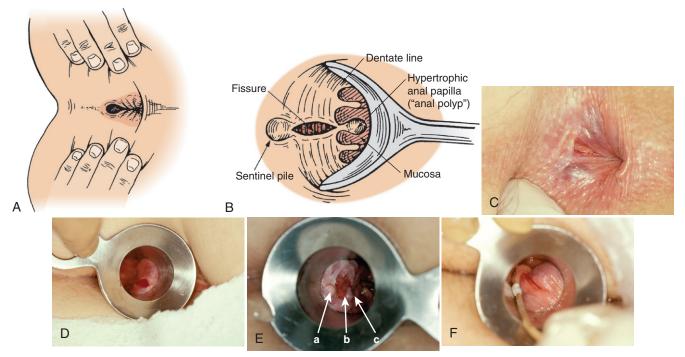

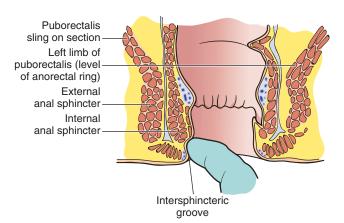

Figure 96-I Anal fissures. Patient is in the left lateral decubitus position. **A,** External examination. Gentle eversion of the buttocks reveals a posterior midline anal fissure. **B,** Anoscopic examination. Chronic posterior anal fissure with a distal "sentinel pile/tag" and a proximal hypertrophic anal papilla at the level of the dentate line. **C,** Superficial anal fissure visualized easily with manual retraction of perianal tissues. **D,** Acute anal fissure diagnosed with use of an Ives slotted anoscope. **E,** Chronic anal fissure. Arrows point to sentinel tag (a), fissure (b), and anal polyp (c). **F,** Large acute anal fissure obscured by hemorrhoids until fold retracted with cotton-tipped applicator. (**C-F,** Courtesy of John L. Pfenninger, MD, The Medical Procedures Center, PC, Midland, Mich.)

because an anal fissure is always located just inside the anal verge. The application of silver nitrate to or the use of electrocautery on the fissure site is *not* recommended and may even exacerbate the symptoms. Anal dilators should *not* be used because of the unpredictable disruption of the anal sphincters and the potential for causing incontinence.

For persistent fissures, a trial of 0.2% to 0.5% nitroglycerin ointment or jelly may be tried. It is recommended that a small amount of this ointment (about the size of a pencil eraser) be applied directly to the fissure three to four times a day, and that it be gently rubbed onto the fissure and not just applied superficially. Patients must be cautioned that if they experience a headache, they are using too much nitroglycerin ointment. Usually, using a lesser amount will eliminate the headaches. The 0.2% to 0.5% nitroglycerin ointment formulation is not yet commercially available (it comes as 2%), but

**Figure 96-2** Sagittal section of the anal canal to illustrate the palpation of the intersphincteric groove by the surgeon's examining finger. (Also see Chapter 97, Clinical Anorectal Anatomy and Digital Examination.)

it can be made up by any reputable local pharmacist from a physician's prescription. The prescription usually reads as follows: "Rx: 0.2% nitroglycerin ointment, DISP: 60 g, SIG: apply small amount to anal fissure, as directed, three to four times a day for 6 to 8 weeks for anal fissure pain." (Be sure to clarify 0.2%, not 2.0%.) Most studies use soft white paraffin to dilute it, or lidocaine or Anusol ointment. If headache does occur, the patient should take an aspirin 1 hour beforehand and lessen the volume applied to the fissure.

Some practitioners now question the efficacy of nitroglycerin and have switched to using *nifedipine gel* 0.2%. The mixture is rubbed in two to three times a day. (Nifedipine gel 0.2%. Mix #10, 20-mg capsules of nifedipine in 100 mL surgical lubricant. Apply to rectal area qid [100 mL].) Some add bethanechol to make 0.1%. K-Y Jelly or 2% lidocaine jelly can be used instead of surgical lubricant.

Both medications pharmacologically relax the anal sphincter to reduce spasm and pain and to assist with the healing process (a "chemical sphincterotomy").

Botulinum toxin (Botox) injected into the anal sphincter is also an option for medical management of anal fissures. The mechanism of action appears to be inhibition of anal sphincter spasm. Initial response is favorable, but long-term follow-up in some studies shows a high recurrence rate. Botox is contraindicated in pregnant and nursing patients and those with neuromuscular disease.

#### Botulinum Toxin Type A Injection Technique

Botulinum toxin type A (Botox) is generally available in 100-U aliquots. (See storage and mixing instructions, Chapter 56, Botulinum Toxin.) The dosage most commonly used for anal fissures is a total of 40 U, with half injected on the right and the remainder injected into the left lateral side of the anal verge. (Remember, most "routine" anal fissures are located anteriorly and posteriorly.) Although various techniques are used, the best results are apparent when the Botox is injected away from the fissure. Usual and customary sterile technique is used, and the perianal area is prepared with povidone—iodine (Betadine). A local anesthetic injection is not

recommended because this will likely cause a similar amount of discomfort as the Botox injection itself. This procedure may be done with or without an anoscope. If the patient is not in too much pain from the anal fissure, a small and well-lubricated anoscope is gently placed into the anal canal in the usual fashion. It is recommended that an open-sided anoscope (Ives slotted anoscope) be used to facilitate palpation of the intersphincteric groove on the right and left sides (see Fig. 96-2). This will obviously require withdrawal and replacement of the anoscope to identify the intersphincteric groove on the contralateral side and may cause significant pain. Each side needs to be injected. The specific technique is to inject a total of 20 U of Botox into the intersphincteric groove using a 30-gauge needle at a depth of approximately 1 cm. (Some choose to inject directly into the internal sphincter.) The two sites of injection are in the middle of both the right and left perianal tissues, directly into the intersphincteric groove. The intersphincteric groove is palpable and usually easily identified on digital examination by slowly withdrawing the gloved examining finger from just within the anal canal out onto the perianal area. In this manner, one should be able to identify this palpable groove without difficulty. It is important to accurately identify the intersphincteric groove site for the subsequent Botox injection into the intersphincteric space.

The effect of botulinum toxin (relaxing the internal sphincter) is not permanent and lasts only 2 to 4 months. If the patient also follows a high-fiber diet, however, this is usually enough time for the fissure to heal. If there is relief but the fissure persists, a second injection can be tried. If there is little relief, a second injection can be made with a smaller dosage of toxin 4 to 6 weeks after the first.

Mild, transient incontinence of gas or feces is not uncommon with this treatment.

#### **Lateral Internal Sphincterotomy**

#### Indications

Lateral internal sphincterotomy is indicated if conservative management has been recommended, the patient has complied for approximately 1 month, and the symptoms of pain or bleeding are still present during and after bowel movements, without improvement.

#### Contraindications

- An atypical location of the fissure (other than anterior or posterior) until a work-up for secondary causes is completed (see previous discussion)
- Preexisting anal incontinence, although the coexistence of an anal fissure and incontinence is uncommon

#### Equipment

The only special equipment required for lateral internal sphincterotomy is an assortment of various-sized anoscopes and a surgical electrocautery unit. The Hill-Ferguson anal retractor is available in small, medium, and large sizes. Any modern electrosurgery device with a cutting and coagulation setting should suffice.

#### Preprocedure Patient Preparation

Although some will perform lateral sphincterotomies in the office, most procedures are performed in day surgery. They take approximately 15 minutes and can be performed in either the left lateral decubitus knee—chest position or in the dorsal lithotomy (pelvic) position.

Inform the patient that lateral internal sphincterotomy is a procedure to divide only the fibers of the *involuntary* internal sphincter to allow the anal canal to relax during bowel movements. The *external* sphincter remains intact and allows for anal control. There is an approximate 5% recurrence rate and a 3% to 5% infection rate. Patients should expect mild to moderate postprocedure pain, which usually is well controlled with oral analgesics. Generally no more than 1 or 2 days is required for recovery, and postoperative pain is minimal compared with the preoperative discomfort from the fissure.

There will be minimal bleeding and spotting for up to 6 weeks after the procedure. With proper technique combined with a thorough understanding of anal sphincter anatomy, alteration of anal continence is uncommon.

As always, before any surgical procedure patients should be made aware of nonoperative treatment options, as discussed previously. If the fissure is not resolved with either conservative or surgical treatment, the patient generally experiences intermittent, persistent symptoms. Fibrosis of the internal anal sphincter can lead to anal stenosis. A subcutaneous fistula originating through the base of a long-standing anal fissure may develop, but is not common.

#### Technique

This is an outpatient procedure, usually performed in the operating room, under monitored anesthesia care using intravenous sedation and local anesthesia. Complete familiarity with the anorectal anatomy is essential.

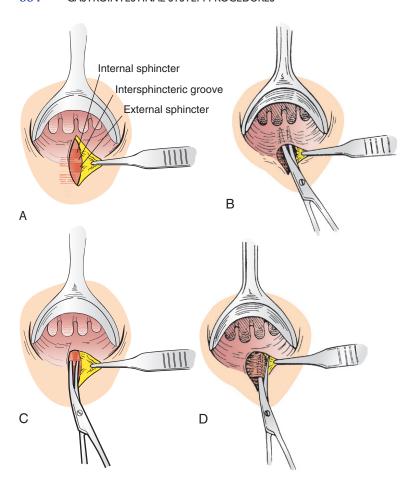

- 1. Place the patient on the operating table in the left lateral decubitus position, with the buttocks just off the edge of the table and the knees flexed. Identify the intersphincteric groove between the internal and external sphincters so that only the fibers of the internal sphincter are divided (see Fig. 96-2); this is done to preserve anal continence for both flatus and feces.
- 2. Use the electrocautery unit to make a superficial 1-cm radial incision just distal and parallel to the palpable intersphincteric groove in the left lateral quadrant of the anal area (Fig. 96-3).
- 3. Grasp the skin edge and clearly identify the intersphincteric groove using the dissecting scissors. The darker-red external sphincter should not be divided or damaged in any way. The lighter-colored internal sphincter is bluntly elevated with forceps. It normally extends 1 to 1.5 cm into the canal.
- 4. Divide the full thickness of the internal sphincter from its distal margin up to the level of the dentate line, which is visible in the anal canal. The internal sphincter is immediately subjacent to the internal hemorrhoidal vessels, and significant bleeding may occur if these vessels are divided. If proper hemostasis cannot be obtained by using pressure or electrocautery, figure-of-eight suture ligation of these vessels may be necessary for persistent bleeding (rare).
- 5. It is very important to leave the primary incision site open and allow it to close secondarily because this technique will almost completely eliminate the chance of a postoperative infection developing at the operative site. If there is a prominent sentinel skin tag ("pile") *distal* to the fissure site or a prominent hypertrophic anal papilla *proximal* to the fissure site, you may excise the tag or the papilla with the electrocautery unit at the time of the sphincterotomy procedure. Generally, no specific operative treatment is performed at the fissure site itself. The average operative time is 15 minutes or less.

#### Postprocedure Patient Education

After lateral internal sphincterotomy, provide a prescription for nonconstipating pain medication (e.g., ibuprofen). The patient should continue to follow a high-fiber diet of at least 30 g of dietary fiber per day and to use psyllium-based powder fiber supplements once or twice a day. He or she should expect some discomfort, slight bleeding, and discharge from the operative site because the wound is generally left open. Bed rest is not recommended, inasmuch as the pain from the sphincterotomy is often minimal and may even be less than that of a severe fissure.

#### **Complications**

- Approximately 5% of patients have nonhealing fissures after sphincterotomy and may need repeat sphincterotomy.
- Various studies have shown a postoperative infection rate of approximately 3% to 5%, and a very small percentage of these patients will go on to develop an associated anal fistula.

**Figure 96-3** Lateral internal anal sphincterotomy using the open technique. The patient is placed in the lateral or the prone (jackknife) position. **A,** A radial incision is made across the intersphincteric groove. A narrow Hill-Ferguson retractor is in place. **B** and **C,** The internal sphincter is separated from the anoderm by blunt dissection. **D,** The internal sphincter is divided. The wound may be closed or left open.

 The most morbid long-term complication is the development of anal incontinence, either of flatus or feces. Postoperative anal incontinence can result from technical operative error during the procedure, whereby muscle fibers other than those of the internal sphincter muscle are divided. Another factor that can contribute to postoperative anal incontinence is unrecognized preexisting anal incontinence.

#### **ANAL FISTULA**

Fistula is the Latin word for "pipe." The medical definition of fistula is an abnormal "pipelike" communication between any two anatomic body parts that do not normally communicate. Anal fistulas are caused by (1) infection, (2) an inflammatory process, or (3) malignancy. The most common cause of a fistula is infection, usually as a secondary complication from a perianal abscess (see also Chapter 107, Perianal Abscess Incision and Drainage). Fortunately, not all patients who present with a perianal abscess develop a subsequent anal fistula. The diagnosis of an anal fistula, like most medical conditions, is made based on a focused history, followed by a careful anorectal examination. Because of the pain involved, if a perianal abscess is present the assessment for an anal fistula should be deferred, unless one is conducting an examination under anesthesia. Treat the abscess first; if symptoms persist, further evaluation is needed.

#### Anatomy

A perianal abscess is adjacent to the anal canal and slowly enlarges to cause increased tissue damage. The abscess likely started as a superficial infection at the dentate line in one of the crypts ("cryptitis"), but rather than spontaneously draining into the anal canal without consequence, the infection spread laterally into the perianal tissues. This now becomes a potential tract, or "pipe," that may develop into a fistula. Development of both a perianal abscess and an anal fistula is increased in the immune-compromised patient (e.g., on steroids) and in patients with IBD (specifically, Crohn's disease), diabetes, status postperianal radiation, and other

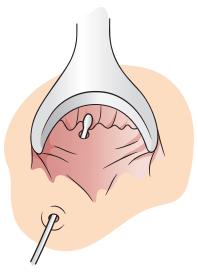

Figure 96-4 Simple fistula tract with blunt fistula probe in place.

conditions. However, fewer than 20% of patients who develop a *single* perianal abscess will ever develop an anal fistula. If, however, a patient presents with a *recurrent* perianal abscess, one must strongly consider the presence of an anal fistula because the odds of a fistula being present are at least 50%, and even higher if the perianal abscess is in the same anatomic location.

An anal fistula may be *simple* or *complex*. A *simple* anal fistula is generally defined as a single tract, as noted in Figure 96-4. A *complex* fistula has multiple tracts and may involve more than two anatomic locations. The discussion here focuses on the more common simple anal fistula.

An anal fistula always has an internal opening and an external opening. By definition, the *external opening* of a simple anal fistula is located on the perianal skin, usually within 3 cm of the anal opening (anal verge), and can be readily visualized on gross examination (see Fig. 96-4). The *internal opening* is within the anal canal and is most commonly located at the level of the dentate line, which is located within 2 cm proximal to the anal verge (Fig. 96-5). The external opening of the fistula may appear to be inflamed, and often

there is a varying degree of discharge. In fact, this discharge may be the symptom that brings the patient in for evaluation, and represents a chronically draining infection. As long as the external opening remains open, a perianal abscess does not develop. The chance of an established anal fistula spontaneously closing without surgical intervention is essentially zero.

Three anal muscles provide anal continence: the internal anal sphincter, the external anal sphincter, and the puborectalis muscle (anorectal ring). Further, the external anal sphincter has three components: subcutaneous, superficial, and deep. In general, involuntary anal continence is provided by the internal sphincter and voluntary anal continence is provided by the external sphincter and the puborectalis muscle, the latter of which essentially comprises the anorectal ring. It is very important to thoroughly understand this anatomy and to clearly identify these three muscles, and the extent of their involvement in any fistula tract, before performing anal fistulotomy.

#### **History and Physical Examination**

A focused patient *history* is very important. The patient likely will have a history of a perianal abscess, with a nonhealing, chronically draining site, usually at the location of the previous perianal abscess. The external opening may not always be active and may swell and drain only infrequently. Typically, however, a patient with an anal fistula presents with a small, palpable, firm nodule within 3 cm of the anal verge, and this site will periodically swell, cause minor discomfort, and drain. The frequency of these symptoms is highly variable.

On *physical examination*, the examiner should carefully and gently palpate all around the anal verge and perianal area. Ask the patient where he or she can feel any swelling, discomfort, or site of drainage. The external opening will not necessarily appear as a true opening, or "hole," and may appear only as a small, erythematous papule (see Fig. 96-5). Usually the external opening will feel indurated, and this firmness may extend for several centimeters from the external opening. Palpate for a subcutaneous tract leading from the external opening toward the anal canal. If present, this suggests a superficial fistula tract and will feel like a small, firm "pipe" just under the skin.

A digital anorectal examination should be completed, with careful palpation all around the level of the dentate line to feel for any

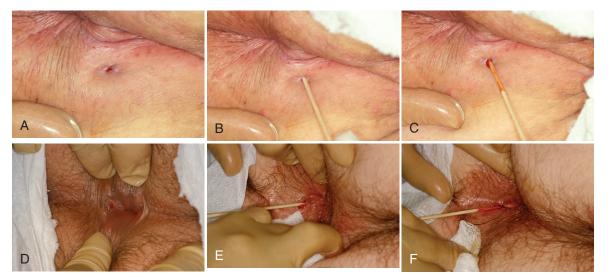

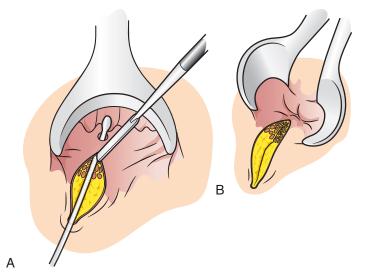

Figure 96-5 The clinical appearance and confirmation of a suspected fistula using a blunt probe. A, Papular, small, pustular-appearing lesion in left buttock. induration or scar tissue, which may suggest the location of the internal opening. Carefully evaluate the anal canal and anoderm with the specific goal of locating any internal opening. Finding the internal opening is ultimately necessary for treatment but is not entirely necessary to establish the diagnosis.

Very gently attempt to pass a blunt fistula probe into the external opening to assess for an established tract. This is usually a small, malleable, 1- to 2-mm-diameter "silver probe" with a tiny bulbous end. The wooden end of a cotton-tipped applicator can also be used, but may be more painful. However, and this cannot be emphasized strongly enough, do not pass the fistula probe against any resistance at all. Creating a false tract will worsen the situation and make treatment much more difficult. If a fistula probe is used, it is most commonly done with the anoscope in the anal canal to offer concurrent visualization of the anoderm and dentate line. The fistula probe is touched to the area of the suspected external opening, and minimal pressure is applied. If this is a true fistula, the probe will literally "drop" into the opening. If it passes easily toward the anal canal, there is really no need to probe further at this time. The suspected anal fistula diagnosis has now been confirmed (see Fig. 96-5).

See Chapter 97, Clinical Anorectal Anatomy and Digital Examination, and the previous discussion of anal fissure and lateral sphincterotomy.

#### Treatment with Seton or Anal Fistulotomy

The treatment for anal fistula is anal fistulotomy. It is absolutely essential to precisely establish the locations of both the internal and external openings of a simple fistula before fistulotomy can be performed. Once these are established, the examiner must carefully assess how much anal sphincter muscle will be divided as a result of simple fistulotomy. If the internal opening is at or distal to (below) the dentate line, a simple fistulotomy may be performed with little to no likelihood of altering anal continence. During fistulotomy, one can generally divide the fibers of the subcutaneous and *superficial* portions of the external and the internal sphincters, usually with little impact on subsequent anal continence.

Anal fistulotomy is usually performed under sedation with monitored anesthesia care. In the left lateral decubitus knee—chest position, with the patient's buttocks just off the edge of the operating room table and with the anoscope in place, local anesthetic with epinephrine is injected along the sides of the fistula tract. This is used primarily for hemostasis and early postoperative comfort. Once the fistula tract anatomy is accurately identified, the blunt fistula probe is placed into the tract with an anoscope in place so both the internal and external openings are clearly visualized, as noted in

Figures 96-4 and 96-5. Fistulotomy may now be performed with electrocautery to divide the tissue overlying the indwelling fistula probe within the fistula tract. Essentially, you are converting an infected "pipe" to an open "ditch." Bleeding points are cauterized. This chronically infected wound is always left open to heal by secondary intention. Dry sterile dressings are applied.

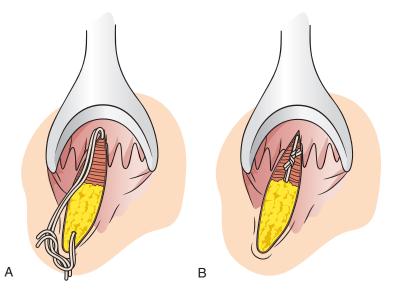

A nearly completed simple fistulotomy, performed with electrocautery, is shown in Figure 96-6. The resulting wound after simple fistulotomy is left open to heal by secondary intention, as noted in Figure 96-7.

Although a seton (a suture placed into the fistula and tied in place) can also be used for simple fistulas, it is usually reserved for the treatment of complex ones. If the course of the fistula tract is lateral to the external sphincter or the internal opening extends above the dentate line, this is not a simple anal fistula, and complete fistulotomy should not be performed. This is now a complex fistula, and surgical treatment should be performed only by an experienced surgeon thoroughly trained in anorectal surgery because of the potential for altering anal continence.

If the internal opening to the fistula tract extends above the dentate line near the anorectal ring, then the fistulotomy becomes a staged operation and will almost certainly involve the use of a seton. The seton is usually a nonabsorbable, doubled, heavy silk suture (see Fig. 96-7A) placed into the fistula tract and tied around to itself to permit a slow cutting through of the fistula tract. The seton is placed into the fistula tract using a blunt fistula probe with an "eye" on the leading end. The long silk seton is threaded through this eye and the probe is replaced into the fistula tract, permitting placement of the doubled suture into the fistula tract. After the probe exits the internal opening, the suture is grasped with a hemostat, and the fistula probe is removed, with the doubled silk suture remaining in the fistula tract. The two ends of the seton are now snugly tied together, as noted in Figure 96-7B, to permit continued slow cutting through the overlying muscle. This produces an inflammatory response and scarring. The few remaining fibers of muscle that overlie the fistula are fully divided, usually with cautery, no sooner than 6 weeks later. The sphincter muscle will not retract and separate now because of the scarring, thereby preserving anal continence.

#### **Contraindications**

- Immunocompromised patient
- History of radiation to fistula location
- Uncontrolled diabetes
- Recent steroid use

**Figure 96-7** Placement of a seton for complex fistula. **A,** The doubled heavy silk suture is threaded through the fistula and tightly tied to put some tension on the skin, **B,** Six weeks later, the overlying remaining tissue is separated using electrocautery and the suture is removed.

Significant medical comorbidities such as severe cardiac or respiratory disease

#### **Common Errors and Potential Complications**

- Dividing excess muscle length overlying the fistula tract, leading to varying degrees of anal incontinence
- Not recognizing as-yet-undiagnosed perianal Crohn's disease
- Not diagnosing and draining an associated occult perianal abscess
- Not recognizing a complex fistula with multiple tracts
- Creating a false fistula tract with overly aggressive use of the fistula probe

#### **Postoperative Management**

After fistulotomy, the patient has an open wound extending into the anal canal. Patients are often fearful of this wound becoming infected because of exposure to fecal material, but an open wound cannot become infected. The patient should shower or tub bathe to irrigate the wound twice a day for the first week, then once a day for 3 to 4 weeks, and apply dry dressings to absorb the expected discharge. The wound will attempt to close prematurely, and the usual wound care measures should be taken to be certain the wound closes from "the inside out." The skin edges must be the last portion of the wound to close; this will dramatically minimize the chance of recurrence. If the skin edges close before the fistula tract is totally closed down by the healing and scarring process, another fistula, often more superficial, has been created. The patient must be instructed that efforts must be made to keep the wound open as long as possible, with complete healing usually occurring within 4 to 6 weeks. The patient should be seen on a weekly basis to ensure this proper healing process.

#### **CPT/Billing Codes**

46020 Placement of seton

46030 Removal of seton

46270 Surgical treatment of anal fistula (fistulectomy/fistulotomy); subcutaneous

46275 Submuscular

46280 Complex or multiple, with or without seton

# CLINICAL ANORECTAL ANATOMY AND DIGITAL EXAMINATION

lames A. Surrell

A practical knowledge of anorectal anatomy is necessary for the proper evaluation and treatment of patients with anorectal complaints, hemorrhoids, and anal fissures. A basic anorectal examination includes *visual inspection* of the perianal tissues and *digital palpation* of the anorectal area. Depending on patient complaints, anoscopy and sigmoidoscopy or colonoscopy may also be necessary. This chapter describes the practical and the clinically important features of anorectal anatomy. See Chapter 98, Anoscopy, for the anoscopic examination.

#### **BASIC ANATOMY**

Figure 97-1 is a diagram of the anatomy of the anal canal and lower rectum.

- Rectum: The distal 10 to 12 cm of the colon.
- Anus: The outlet of the gastrointestinal tract, consisting of the lower 6 to 8 cm of the bowel.
- Anal verge: Most distal extent of the anal canal, just at the opening.
- Dentate or pectinate line: The squamocolumnar junction located 2 to 3 cm proximal to the anal verge where there is an abrupt change from squamous, sensory anoderm to columnar or mucosal epithelium. There are no sensory nerve fibers above the dentate line, only visceral-type fibers that sense pressure.
- Transitional zone: Composed of mixed columnar and squamous epithelium; where the anal canal merges with the rectum.
- Internal sphincter: The innermost circular muscle.
- External sphincter: Located outside (lateral to) the internal sphincter. Note that the external sphincter is external to the internal sphincter not only from a medial to lateral aspect, but from a cephalic to caudal aspect at the anal verge.
- Puborectalis muscle (anorectal ring): Located about 1 to 2 cm above
  the dentate line. The distal rectum and anal canal are surrounded
  by two sleeves of circular muscles. This palpable anorectal ring
  represents the puborectalis muscle, which encircles the very distal
  rectum from its anterior point of attachment at the pubis.
- "Valves of Houston": These are not really "valves" but just folds of mucosa. There are generally three located at approximately 8, 11, and 13 cm (inferior, middle, and superior, respectively).
- Anal papillae: The mucosal tips of the anal glands at the dentate line. (They can become hypertrophied and elongated and be confused with a polyp.)
- Anal crypt: A small pocket along the dentate line. Usually the site of cryptitis, which can lead to a fistula.
- Anal glands: Located at dentate line. They secrete mucus to lubricate the canal and can become infected or plugged (cryptitis).
- Columns of Morgagni: Folds of tissue above the anal crypts/dentate line.

- Internal hemorrhoids: Located at and just proximal to the dentate line.
- External hemorrhoids: Located distal to the dentate line at the anal verge.
- Arteriovenous vessels: Located above, below, or at the dentate line, or both above and below the dentate line.

#### **PATIENT POSITION**

A complete anorectal examination can be accomplished with the patient on the examining table in the left lateral decubitus position (Fig. 97-2). The patient's knees are flexed and drawn toward the chest and the buttocks are drawn toward the examiner to a point just slightly off the table. The patient's head and shoulders should remain well toward the middle of the examination table so that the patient is confident that he or she will not fall. This position also directs the axis of the anal canal and rectum directly toward the examiner. Alternatively, the rectum may be examined with the patient in the pelvic position after a genital examination or in a flexed position while bending 90 degrees over an examination table.

#### **EXTERNAL ANAL EXAMINATION**

After appropriately advising the patient, visually inspect the external anus. Look for any sign of perianal inflammation that may suggest pruritus ani or other dermatologic conditions. Gently separate the buttocks; this will generally evert the anoderm to a sufficient degree so that a posterior or anterior anal fissure may be directly visualized.

If there is a *sentinel skin tag* present in either the posterior or anterior midline, be diligent in evaluation for a fissure, especially if the history is consistent with anal fissure (see Chapter 96, Anal Fissure and Lateral Sphincterotomy and Anal Fistula). If present, anal skin tags, perianal abscess, or thrombosed external hemorrhoids should be readily visible at this time. Internal and external hemorrhoids are classically located in the right anterior, right posterior, and left lateral quadrants.

Internal hemorrhoids are located at and just proximal to the dentate line. Because they are above the dentate line, any condition involving them is usually painless. External hemorrhoids are located distal to the dentate line at the anal verge, and pathology or treatment in this area is generally quite painful. Hemorrhoids are collections of arteries and veins that, if not enlarged, represent normal anatomy and are not considered varicosities (see Chapter 106, Office Treatment of Hemorrhoids).

It is recommended that clinical anorectal findings be described in terms of the anatomy (i.e., right anterior, right posterior, left anterior, left posterior, right lateral, and left lateral) to provide consistency, regardless of the position of the patient.

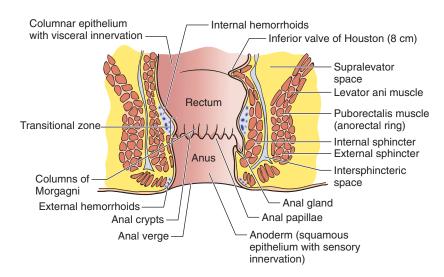

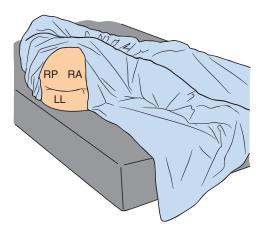

Figure 97-I Anal and rectal anatomy.

#### **DIGITAL ANORECTAL EXAMINATION**

Inform the patient that the anus will be touched with a well-lubricated, gloved examining finger. Apply gentle pressure to the anal verge to allow the examining finger to enter the anal canal. If an anal fissure is present, you may feel palpable induration, most commonly in the posterior midline and less commonly in the anterior midline. Increased tone will also be noted. If the patient complains of severe pain, do not persist, because you will lose the patient's confidence. You may wish to reattempt the digital examination after applying 5% lidocaine ointment to the anus and waiting 10 to 15 minutes. The most common causes of severe anal pain on examination are a deep symptomatic anal fissure or a perianal abscess. Fissures are found most commonly anteriorly and posteriorly. Rarely, you may need to consider offering the patient an examination under sedation or refer for examination under anesthesia. Consciously palpate all around the anorectal area (360 degrees).

In men, assess the prostate gland with your gloved examining finger in the anal canal.

To assess continence and anal sphincter function, flex your index finger slightly posteriorly and ask the patient to "squeeze down" as if to try to stop a bowel movement. If the patient has normal anatomic sphincter function, you will feel the tightening of the distal extent of the external sphincter at the base of your examining finger.

**Figure 97-2** Placing the patient in the left lateral decubitus position (Sims' position). Digital examination, flexible sigmoidoscopy, and most anorectal procedures can be performed in this position. LL, Left lateral hemorrhoidal quadrant; RA, right anterior; RP, right posterior.

The puborectalis muscle of the anorectal ring will also contract, pulling the tip of the examining finger from posterior to anterior. You should then be able to sweep the examining finger around the circumference of the distal rectum at the level of the anorectal ring and note the point of fixation of the puborectalis muscle at the symphysis pubis. Advise the patient to relax as the examination continues.

In general, internal hemorrhoids and the dentate line are not palpable to the gloved examining finger. However, a large hypertrophic anal papilla present at the level of the dentate line may be palpable. If necessary, obtain a small sample of stool on the tip of the gloved examining finger for occult blood testing.

The procedure for anoscopic examination can be found in Chapter 98, Anoscopy. Anal fissures are discussed in Chapter 96, Anal Fissure and Lateral Sphincterotomy and Anal Fistula.

#### **ANAL CONTINENCE**

The external sphincter and puborectalis muscle of the anorectal ring are the two muscles generally thought to afford *voluntary* anal continence. The external sphincter extends from the anal verge to the anorectal ring. The anorectal ring consists primarily of the puborectalis muscle, which encircles the very distal rectum. From a practical standpoint, it is generally accepted that either an intact functional external sphincter or an anorectal ring can provide near-perfect anal continence. The internal sphincter plays little role in maintaining voluntary anal continence. This is important when counseling patients during consideration of surgical treatment of anal fissures (see Chapter 96, Anal Fissure and Lateral Sphincterotomy and Anal Fistula).

#### **SUMMARY**

A practical understanding of the anatomy of the anal canal is essential to conducting an adequate anorectal examination. Lesions commonly seen may include pruritus ani or perianal dermatitis, anal fissures, fistulas, thrombosed external hemorrhoids, prolapsing bleeding internal hemorrhoids, hypertrophic anal papillae, perianal abscess, pilonidal disease, condylomata, polyps, cancer, and others. When anal continence is an issue, the physician must be able to evaluate the function of the external sphincter and of the puborectalis muscle of the anorectal ring on digital anorectal examination. With appropriate patient preparation and technique, the anorectal examination should not be an uncomfortable or painful experience. See Chapter 98, Anoscopy, for a description of the anoscopic examination.

## **ANOSCOPY**

Peter L. Reynolds • Thad Wilkins

Anoscopy is a common procedure in both ambulatory and emergency medical care. It is used primarily to evaluate the patient with perianal and anal complaints. It may also be performed just before or after withdrawing the colonoscope or flexible sigmoidoscope. Chapter 97, Clinical Anorectal Anatomy and Digital Examination, includes a review of clinical anatomy. High-resolution anoscopy (HRA) refers to an evolving technique to evaluate patients at high risk for anal human papillomavirus (HPV) infection. This includes men who have sex with men and human immunodeficiency virus—infected women with cervical dysplasia. With HRA, the anus is stained with acetic acid and then evaluated using magnification—usually a colposcope (see Chapter 99, High-Resolution Anoscopy).

#### **INDICATIONS**

- Initial evaluation of rectal bleeding
- Anal or perianal pain
- Perianal itching (pruritus ani)
- Anal discharge
- Prolapse of the rectum
- External or internal hemorrhoids
- Fissures in ano
- Fistulas in ano
- Painful digital rectal examination
- Perianal condylomata
- Palpable masses on digital examination
- In association with sigmoidoscopy and colonoscopy (screening or diagnostic)
- Evaluation of intra-anal trauma
- Follow-up of inflammatory bowel
- Retrieval of foreign body
- Evaluation of sexual abuse
- Fecal impaction
- Anal polyps, cancer
- Screening for anal HPV in high-risk individuals

#### **CONTRAINDICATIONS**

- Unwilling patient
- Severe debilitation
- Acute myocardial infarction or similar cardiovascular condition
- Acute abdomen (relative contraindication)
- Marked anal canal stenosis
- Severe pain

#### **EQUIPMENT**

- Anoscope
- Light source
- Gloves
- Lubricant
- Large-tipped cotton swabs

- Biopsy forceps, if needed (the cervical biopsy forceps or the flexible wire biopsy forceps used during sigmoidoscopy or colonoscopy work well)
- Monsel's solution (ferric subsulfate solution)
- 3% acetic acid solution (HRA only)
- Colposcope with 10× to 40× magnification (HRA only)

The anoscope consists of two parts: a hollow, gently tapering cylinder and a solid obturator that fits inside. The components are made of disposable plastic or reusable metal (Fig. 98-1). Clear plastic anoscopes may provide better visualization of the rectal and anal mucosa than opaque devices, but they do tend to compress the tissues and may obscure some findings. The size varies from 7 to 10 cm in length. They may or may not have handles. The distal diameter is approximately 2.5 cm.

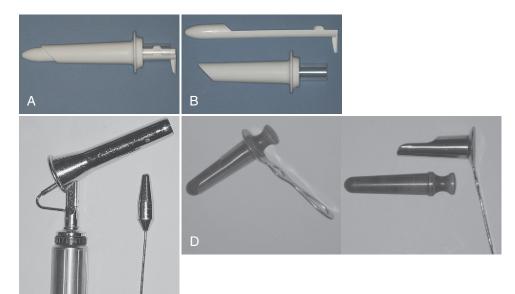

Some anoscopes are readily attachable to battery light sources. Others require an external light source (e.g., a gooseneck lamp or headlight).

The *Ives slotted anoscope* is made of metal but has an open slot on one half of the upper side of the device (see Fig. 98-1D and E). The slot provides an unobstructed view of the walls of the anal canal. This instrument is extremely useful not only for evaluation but when treating various conditions. The advantage of the slotted instrument is that the mucosa is not compressed; thus, small lesions and hemorrhoids may be more readily visible and treated. The diameter is also larger than most other anoscopes, and instruments are more easily manipulated within the lumen. Rather than looking through the end of the tube, the operator can visualize the mucosal wall in a more direct fashion (Fig. 98-2).

#### PREPROCEDURE PATIENT PREPARATION

Patients dread inspection of the anal canal. They perceive this examination as unpleasant and uncomfortable, if not painful. There are always concerns of embarrassment. This mandates that the patient be prepared mentally for what is involved. However, these concerns should not dissuade the clinician from doing the examination when it is indicated. Far too often the "assumed" diagnosis by the patient or the physician is made without a visual examination completed. This is not only unacceptable, it can place the patient at great risk for missed diagnoses such as cancer, inflammatory bowel disease, and other significant problems. The patient must be cooperative and relaxed. Frank admission that the procedure will be unpleasant and uncomfortable, but not painful, is helpful. Explain the reasons necessitating the examination and the implications of not performing it. Reassure the patient that there are no significant complications resulting from anoscopy alone. However, if a biopsy sample is obtained or a lesion is removed, there may be some bleeding. If the biopsy is from below the dentate line, it will also be painful and local anesthetic will be needed.

If the reason for the examination is to evaluate anal pain (e.g., possible fissure), patients can be extremely tender and apprehensive. In addition, the anal sphincter contracts, making the examination

**Figure 98-1** Disposable plastic opaque anoscope requiring external light source with obturator in place (**A**) and obturator removed (**B**). Reusable type for use with battery-powered light source; inserting trocar has been removed (**C**). **D**, Ives slotted anoscope with obturator in place (*left*) and obturator removed (*right*). The Ives slotted anoscope provides the best visualization and the most operative space for any interventional procedures.

difficult. Application of a topical anesthetic, such as 5% lidocaine, 30 minutes before the examination can markedly reduce discomfort (see Chapter 10, Topical Anesthesia). If pain is so severe that the examination needs to be deferred, the presumptive diagnosis is an anal fissure, but the examination, perhaps at a later date after treatment, is necessary to confirm that there is no other pathologic process.

#### **TECHNIQUE**

C

An assistant is helpful and gender-appropriate chaperones recommended. Both physician and assistant must wear gloves on both hands. An enema is usually not needed but may be helpful. Consider eye protection.

1. Place the patient in the left lateral position and drape. This position is most comfortable for the patient and is adequate in

**Figure 98-2** Hypertrophic papilla found on anoscopic examination (Ives slotted anoscope). This is often palpable as a firm mass.

- at least 95% of situations. At times, placing the patient in stirrups or in the head-down position may be indicated.
- 2. Have the assistant separate the glutei laterally, allowing full visibility of the perianal area. Alternatively, have the patient pull up on the right gluteus. Check for any obvious lesions and possible fistulous tracks.
- 3. Inspect the tissue closely. Ask the patient to bear down, and observe for hemorrhoid or polyp prolapse.
- 4. Perform a careful circumferential digital examination with an index finger that has been lubricated with K-Y Jelly or 2% lidocaine jelly. Note the sphincter tone. (See Chapter 97, Clinical Anorectal Anatomy and Digital Examination.)
- 5. In male patients, palpate the prostate for size and masses.
- 6. Lubricate the anoscope well with K-Y Jelly with the obturator in place (see Fig. 98-1).
- 7. Gently insert the anoscope into the anal aperture, gradually overcoming the resistance of the sphincters. Advance the instrument in the direction of the umbilicus until the full length of the anoscope is inserted (subject to patient acceptance and tolerance). The procedure is better tolerated and accomplished by asking the patient to gently take a few deep breaths at the beginning of the procedure and to bear down just slightly. If the patient complains of pain with insertion, the quality and location should be noted and correlated with clinical symptoms.
- 8. After inserting the full length of the instrument, remove the obturator so that the mucosa of the anal canal can be visualized. Fecal material is often encountered and can be removed with a large swab. Note the gross appearance of the mucous membrane, the pectinate (dentate) line, and the vasculature, as well as the presence of blood, mucus, pus, hemorrhoidal tissue, and so forth.
- 9. Gradually withdraw the instrument with the obturator still removed. Observe the anal canal as the anoscope is extracted. Figure 98-3 shows a small, bleeding internal hemorrhoid as seen through the opening of the anoscope. For reference, the same area is shown in Figure 98-4 as visualized through a retroflexed colonoscope. With opaque devices, rotate the long-cylinder anoscopes to the right and left to ensure that the entire canal has been visualized. The Ives slotted instrument must be

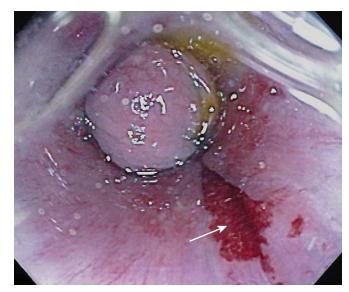

**Figure 98-3** Pectinate (dentate) line (*arrow*) and small bleeding internal hemorrhoid (*asterisk*) seen as anoscope is slowly withdrawn.

inserted four times so that each quadrant can be examined. Keeping it in place for a minute or two allows any hemorrhoids that are present to engorge with blood and be more readily visible. Do not rotate this instrument because it causes discomfort. The clear plastic anoscope allows the examiner to visualize the mucosa both through the anoscope as well as at the opening of the device. Figure 98-5 shows an anal fissure as seen through the wall of the anoscope.

10. If a biopsy specimen is to be obtained, a variety of long-handled biopsy instruments can be used. The instruments used for cervical biopsy work well (obtain the smallest "bite" possible). The clinician can also use the biopsy forceps normally used for flexible sigmoidoscopy. In this case it is applied with direct visualization of the areas. Expect some bleeding, but it is usually readily controlled with Monsel's solution or silver nitrate and natural pressure when the anoscope is removed. Stay superficial; only 3 or 4 mm of tissue is necessary.

**Figure 98-4** View of same patient as in Figure 98-3 using a retroflexed colonoscope. Pectinate line is indicated by the *arrow*. (Note that internal hemorrhoids are flattened by insufflated air.)

**Figure 98-5** Anal fissure seen through the wall of a clear plastic anoscope (arrow).

- 11. HRA: After an anoscope is inserted in the rectum, gauze soaked in 3% acetic acid solution is applied to the rectal mucosa. After 1 minute, the gauze is removed and the anoscope is repositioned as needed. Visualization is performed using a colposcope at 10–40x magnification. Abnormal lesions can be sampled and hemostasis obtained with Monsel's solution. An anal Pap smear should be done in conjunction with HRA. Additional references on this subject are included in this chapter and in Chapter 99, High-Resolution Anoscopy.
- 12. Complete the procedure form (Fig. 98-6).

#### COMPLICATIONS

Anoscopy, when performed gently, has few if any complications. Likely or possible complications include discomfort, tearing of the perianal skin or mucosa, and abrasion or tearing of hemorrhoidal tissue. There may be bleeding after biopsy, but infection almost never occurs.

#### POSTPROCEDURE PATIENT EDUCATION

Thoroughly explain the findings to the patient, and use pictures and drawings in the explanation. Discuss the etiology, treatment, and course of resolution of each finding as thoroughly as possible.

## HIGH-RESOLUTION ANOSCOPY

J. Michael Berry • Naomi Jay

High-resolution anoscopy (HRA) is the examination of the anus and perianal region using a colposcope for magnification. It is a technique pioneered at the University of California, San Francisco (UCSF) in the Anal Neoplasia Study to determine the natural history of human papillomavirus (HPV)–related anal neoplasia. Similar to examination of the cervix, 3% acetic acid is applied to the anus and a colposcope is used to carefully examine the anal mucosa and perianal skin. Lesions can be identified using standard colposcopic criteria and sampled for histologic confirmation.

High-risk HPV types are found in up to 93% of anal cancers. High-grade anal intraepithelial neoplasia (HGAIN), including AIN grade 2 or 3 (moderate or severe dysplasia) or carcinoma in situ, are considered potentially precancerous lesions. It is believed that identification and eradication of HGAIN may prevent anal cancer, but studies demonstrating this principle have yet to be performed. The anus and cervix are similar biologically: both have a squamocolumnar junction, both are susceptible to the same types of HPV, and both demonstrate a similar spectrum of lesions. Because of these similarities, techniques for cervical cancer screening have been adapted for the anus.

În the United States in 2009 it was estimated that there were 5290 new cases of anal cancer, 2100 in men and 3190 in women. The incidence in the general population is 1.5/100,000. In human immunodeficiency virus (HIV)—negative men-who-have-sex-withmen (MSM), before the HIV epidemic, the incidence was estimated to be 35/100,000. Since the introduction of highly-active antiretroviral therapy, studies demonstrate an incidence twice that in several cohorts of HIV-positive patients, ranging from 78.2 to 92/100,000. The relative risk for anal cancer is increased to 4.68 (95% confidence interval 3.87–5.62) in women with a history of grade 3 cervical intraepithelial neoplasia (CIN) compared with women with no history.

Anal HPV infection can be found in more than 90% of HIV-positive MSM and approximately 60% of HIV-negative MSM. HRA with biopsy of suspect lesions found HGAIN in 52% of HIV-positive MSM, and in 16% of HIV-negative MSM at baseline in a cohort of men enrolled in the UCSF Anal Neoplasia Study between 1998 and 2000. A more recent population-based sample found rates of anal HPV infection of 57% in HIV-negative versus 88% in HIV-positive MSM. HGAIN was detected during HRA-guided biopsy in 25% and 43%, respectively.

In a study of 470 HIV-positive and 185 HIV-negative women, anal HPV was found in 80% of HIV-seropositive women compared with 50% of HIV-seronegative women. HGAIN was found in 9% of HIV-positive women and in 1% of HIV-negative women. In HIV-negative women with a history of CIN, 58% had anal HPV (slightly more than 30% had cervical HPV) and 15% had abnormal anal cytology. In women without a history of CIN who presented for sexually transmitted infection testing, 53% had anal HPV and 11% had anal squamous intraepithelial lesions. A group of 40 women with vulvar cancer were compared to 80 age-matched control women who were all examined with HRA. Coexistent HGAIN in 15 patients and 1 invasive anal cancer were found in

the patients with vulvar cancer, compared with no cases of HGAIN in the control subjects.

Markov modeling demonstrated that anal cytology for anal cancer screening is cost effective every 2 to 3 years in HIV-negative MSM and every 1 to 2 years in HIV-positive MSM. In spite of these data, except for the state of New York, there are no official public health recommendations for screening programs. There are several reasons why routine screening programs have not been recommended in spite of convincing epidemiologic data. Data are just emerging demonstrating that HGAIN can progress to cancer. Currently, no controlled clinical trials have been initiated or completed demonstrating that screening and treatment of HGAIN prevent anal cancer. Another main limiting factor for screening is the lack of providers trained and experienced in performing HRA.

Ideally, HRA should be used to identify and target lesions for treatment because these lesions are largely invisible without the application of acetic acid and magnification. Data from several papers demonstrate that HGAIN can be effectively eradicated in many patients using an office-based procedure known as *infrared coagulation*. Patients with more *extensive lesions* are effectively managed with a combination of targeted surgical therapy of HGAIN guided by HRA coupled with office-based infrared coagulation to manage the inevitable recurrences. There was no evidence of HGAIN in 192 of 246 (78%) patients treated with this combined approach at their last follow-up visit.

Screening HIV-positive MSM with anal cytology and referring those with any level of cytologic abnormality can be recommended based on demonstrated cost effectiveness and increased prevalence of HGAIN and anal cancer. Some providers believe that if resources are available, HIV-positive MSM could be examined with HRA to maximize detection of HGAIN. For similar reasons, all MSM could be offered anal cytology screening. Because of the known association between high-risk HPV, high-grade CIN and vulvar intraepithelial neoplasia, and cervical and vulvar cancer, anal cytology screening may also be useful in women with these findings, followed by referral for HRA for any cytologic abnormalities.

Solid organ transplant recipients are at increased risk of anogenital cancer and may benefit from screening as well. Patients with *perianal condylomata* regardless of sex or sexual orientation may also benefit from screening.

Anal cytology screening in patients at increased risk for anal cancer requires that providers experienced in performing HRA be available to follow up on any abnormal results. HRA is a necessary requisite for a successful program in managing anal neoplasia because in the absence of palpable or visible lesions such as condylomata or anal masses, most HGAIN lesions are not visible or palpable.

Formal programs for certification, training, and standards in performing HRA have been created only recently. The first course in HRA was conducted in San Francisco in conjunction with the American Society for Colposcopy and Cervical Pathology (ASCCP) and coupled with this group's Comprehensive Colposcopy course in August 2005. It is now offered annually.

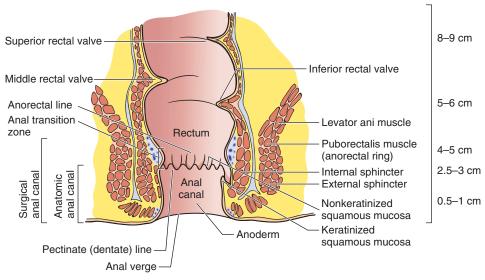

Figure 99-1 Anal anatomy.

Before learning HRA, providers should attend a formal colposcopy course and a formal didactic course in HRA, if possible. After basic colposcopy skills have been gained, attending an existing anal neoplasia clinic and spending several days observing HRA and the performance of anal biopsies in multiple patients is helpful. Further experience can be gained only by performing the procedure. Novices are advised to keep a logbook of all of their patients and to record their clinical and colposcopic impression. This can then be correlated with the cytologic and histologic results when they become available. This allows not only for patient follow-up, triage, and disposition, but for the clinician to develop and hone his or her clinical skills.

#### **ANATOMY**

Like the cervix, the anus has a *transformation zone* (AnTZ) and a *squamocolumnar junction* (SCJ) where the anal squamous mucosa is adjacent to the colon columnar epithelium (Fig. 99-1). The SCJ is above the *dentate* or *pectinate line*. A similar process of squamous metaplasia occurs in the AnTZ, and dysplastic changes can occur during this dynamic time of transformation. When performing anal cytology, it is important to sample all areas of the AnTZ, just like in the cervix, so that cells are sampled from all areas. An adequate cytologic sample will have columnar or squamous metaplasia, which indicates that the AnTZ was sampled.

#### **INDICATIONS**

Other than for a formal screening program for those at risk (MSM, anal-receptive intercourse, women with high-grade cervical and vulvar dysplasias/cancers, and organ transplant recipients), reasons patients may be referred for HRA include the following:

- Abnormal anal cytology of any degree
- Incidentally detected condylomata or HGAIN during colonoscopy
- Before hemorrhoidectomy or surgery for other benign anorectal conditions to rule out concurrent disease and allow treatment at the same time
- Perianal lesions, including condylomata, hyperpigmented lesions typical of Bowen's disease, erythematous lesions, ulcerations, or masses
- Evaluation of anal symptoms such as irritation, itching, pain with bowel movements, bleeding or discomfort with receptive intercourse

- Self-detected lump or bump
- Prior history of anal condylomata, HGAIN, or anal cancer
- CIN, vulvar dysplasia

#### CONTRAINDICATIONS

Severe neutropenia (<1000) is the one absolute contraindication to performing HRA. Current or past neutropenia or thrombocytopenia may indicate the need to defer biopsies or have current blood work available to determine the safety of performing biopsies.

#### **EQUIPMENT AND SUPPLIES**

Most of the equipment is the same as that used for a cervical examination (see Chapter 137, Colposcopic Examination). A procedure tray for HRA is shown in Figure 99-2. The tray includes the following:

Figure 99-2 A typical equipment tray for high-resolution anoscopy.

- Cytology liquid medium (or conventional slide with fixative solution)
- Dacron swab ("Q tip")
- Anoscope (disposable plastic or sterilized metal)
- 3% acetic acid
- Nonsterile cotton swabs
- Nonsterile scopettes
- Nonsterile 4 × 4 gauze pads
- Lugol's solution
- K-Y jelly mixed with 1% to 5% lidocaine gel
- A 4 × 4 gauze wrapped around a cotton swab

#### **Additional Equipment for Biopsies**

- Formalin bottles
- Baby Tischler or mini-Townsend cervical punch biopsy or endoscopy forceps
- Monsel's solution

#### **Additional Equipment for Perianal Biopsies**

- 1% lidocaine with epinephrine and sodium bicarbonate (2 mL per 10 mL of lidocaine)
- 22-gauge needle (to fill syringe)
- 30-gauge needle (for injection)
- 1-mL syringe
- Small pickup Adson forceps, generally without teeth, punch biopsy
- Silver nitrate used for hemostasis

#### Colposcope

The following specifications are helpful for performing HRA with a colposcope:

- Double objective lens with magnification up to 25×
- Angled eyepieces (the straight-on view is ergonomically difficult for HRA unless the height of the table is adjustable)
- Side-swing arm

#### PREPROCEDURE PATIENT EDUCATION

Patients should be told to refrain from inserting anything per anus for 24 hours before the procedure. This includes anal sex and insertion of any toy, medication, or enemas.

When discussing the procedure with patients, explain that a normal examination with biopsies will take 10 to 20 minutes. There are no pain nerve endings in the anal canal above the dentate line, only below it. The majority of lesions are above the dentate line and so biopsies are rarely felt beyond a sensation of minor pressure. The examination itself is not painful, but often there is mild discomfort associated with the pressure of the anoscope on the sphincter. Incontinence is rare, but patients should be told that the pressure will make them feel as if they need to have a bowel movement.

Medical history should include prior anal diseases, including abnormal cytology results, diagnoses of condylomata, low-grade anal intraepithelial neoplasia (LGAIN), HGAIN, or cancer, and any treatments used. In women, prior or current genital HPV-associated disease is important. A history of rectal abscesses, fistula tracts, fissures, or hemorrhoids can help determine potential sources of pain, bleeding, and scar tissue. Evaluate for history of immunosuppression or immune-suppressing drug therapy for organ transplantation, lupus, Crohn's disease, or any disease requiring ongoing steroid therapy.

Complications such as severe bleeding and infection are rare. Scant bleeding after a biopsy may occur over a 1- to 2-day period and is not cause for alarm. Vasovagal reactions occur rarely.

#### **PROCEDURE**

#### **Anal Cytology**

Anal cytology results are categorized according to the Bethesda classification system using terminology similar to that for cervical cytology. Anal cytology sensitivity for detection of anal neoplasia is comparable to that of cervical cytology, with a 25% or higher miss rate. The goal of anal cytology screening is to identify patients with HGAIN, who can then be treated. Cytology should be repeated every 2 to 3 years in low-risk patients and more frequently in high-risk patients (Fig. 99-3).

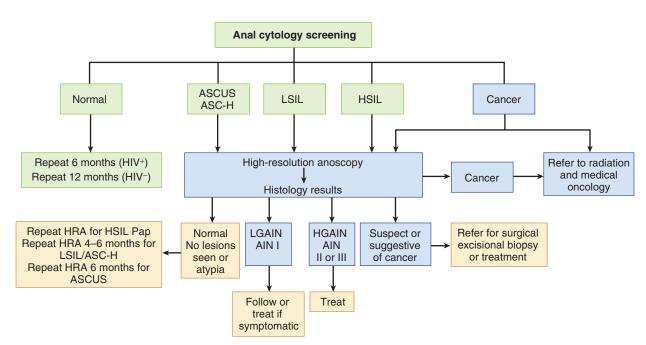

Figure 99-3 Anal cytology screening triage algorithm. AIN, anal intraepithelial neoplasia; ASC-H, atypical squamous cells, cannot exclude high-grade lesion; ASCUS, atypical squamous cells of undetermined significance; HGAIN, high-grade anal intraepithelial neoplasia; HIV, human immunodeficiency virus; HRA, high-resolution anoscopy; HSIL, high-grade squamous intraepithelial lesion; LGAIN, low-grade anal intraepithelial neoplasia; LSIL, low-grade squamous intraepithelial lesion.

Anal cytology is used to identify those populations and individuals most likely to have HPV-associated disease. An anal cytology result of ASCUS (a typical squamous cells of undetermined significance) or higher grade is considered abnormal, and HRA is advised based on research showing that the sensitivity for cytology screening improved when ASCUS was used as the threshold for abnormal. The cytology result is considered a screening test and is not diagnostic. The diagnosis will be provided through HRA-identified and sampled lesions. Figure 99-3 provides a screening and HRA algorithm.

#### **Performing Anal Cytology**

The anal cytology specimen should be obtained before HRA and any digital examination in order to obtain the highest yield of cells without interference from lubricants.

- The left lateral position provides adequate comfort for the patient and good visualization for the clinician. However, the lithotomy position can be used, and if a proctology table is available patients can lean forward and lie prone.
- 2. Gently separate the buttocks. Patients can hold their buttock to facilitate the view.
- 3. Insert a moistened Dacron swab approximately 4 to 5 cm into the anus. For most patients this will ensure adequate sampling of the AnTZ. (However, the depth for location of the AnTZ and SCJ varies in individuals. In some it is a significant distance in [5 to 6 cm], whereas in others it is just inside the anal verge.) The swab should be inserted just past the internal sphincter until it abuts the rectal wall. If initial resistance is encountered, change the angle of the swab and reinsert. It should be possible to insert the swab with very little discomfort. Use a nonscored Dacron swab because the scored swabs can break when pressure is applied (Fig. 99-4).
- 4. While slowly withdrawing the swab, apply pressure against the anal sidewalls and sample the entire circumference of the canal, going in a circular motion. This facilitates sampling cells from all aspects of the canal. A slight bending in the "stick" while removing the swab indicates that adequate pressure is being used. Count slowly to 10 as you remove it to maximize the yield of exfoliating cells.
- 5. Preserve the sample quickly on slides for a conventional smear, or in liquid medium. Fewer cells exfoliate from the anal canal than the cervix, and air-dried artifacts can be more problematic. If using conventional slides it is better to quickly immerse the slides in cytology fluid rather than spraying them.
- Digital rectal examination may be the most sensitive way of detecting an actual cancer and therefore should be performed in all patients after a cytologic sample has been obtained.

**Figure 99-4** Insertion of Dacron swab for anal cytology. Retracting the buttocks facilitates more comfortable insertion of the swab.

**Figure 99-5** Insertion of the acetic acid—soaked gauze through the anoscope. The anoscope is then withdrawn, leaving the gauze in place.

#### **Performing High-Resolution Anoscopy**

After an abnormal cytology result, or for a routine baseline examination in an at-risk individual, HRA is used to inspect the AnTZ, SCJ, anal canal, anal verge, and perianal areas. The clinician identifies lesions based on clinical impression and obtains biopsies to determine the level and extent of disease for treatment.

Although basic colposcopy skills form a foundation for HRA, there are several unique differences in the skill sets required to accurately recognize lesions and to manage anal neoplasia. Mucosal folds and hemorrhoidal bulges make visualization of the entire SCJ difficult because it is common for lesions to be hidden within the folds. Additional acetic acid must be applied during the examination to the entire SCJ and canal. Lesions may be more subtle in their presentation, with variations of acetowhitening and epithelial changes. Similar to colposcopy, having a low threshold for taking biopsies is necessary, particularly in the early stages of learning HRA.

- 1. The same position can be used for HRA as for the cytologic collection. If a cervical examination is also being performed, the lithotomy position can be used, but most women prefer to switch to the left lateral position for HRA. A prone position can be used if an overhead colposcope is available. If in the lithotomy position, patients should lie as close to the bottom edge of the table as possible to ensure adequate focusing of the colposcope. In the left lateral decubitus position, they should lie as close to the edge of the table as possible with the anus directed at the examiner. A power table facilitates the use of a colposcope.
- 2. After a cytologic sample has been obtained (if indicated), perform a digital rectal examination. Lubricate the anal canal with K-Y jelly mixed with 2% to 5% lidocaine gel. Palpate for warts, masses, ulcerations, fissures, and focal areas of discomfort or pain. The presence of hard, fixed, or painful lesions should increase your index of suspicion for cancer because warts and

**Figure 99-6** The colposcope is focused with one hand while the other hand holds the anoscope in place.

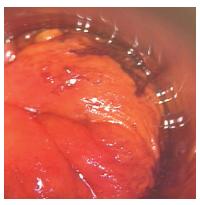

**Figure 99-7** The anal transformation zone (AnTZ) is seen as a thin white line adjacent to the columnar epithelium. The anal mucosa is lighter than the colon, which is darker red.

- hemorrhoids do not usually present in these ways. Make note of scar tissue, which will feel less elastic and may have thickening, ridges, and firm areas. Prior abscess, fistula repair, and surgery for warts are possible causes for scarring.
- 3. Insert a well-lubricated anoscope and remove the obturator (see Chapter 98, Anoscopy). Wrap a 4 × 4 gauze that has been soaked in acetic acid around a cotton swab and insert it through the anoscope. Remove the anoscope, leaving the cotton swab—wrapped gauze inside (Fig. 99-5).
- 4. Allow the acetic acid to soak for 1 to 2 minutes; 3% acetic acid is better tolerated in the anus but 5% can be used.
- 5. Remove the gauze and reinsert the anoscope with the obturator. Remove the obturator. Control the anoscope with one hand, while focusing the colposcope with the other hand (Fig. 99-6).
- 6. Observe through the anoscope as you slowly withdraw it. Focusing the colposcope requires manipulating the anoscope and colposcope simultaneously so that the anus is always in focus.
- 7. Withdraw the anoscope until the AnTZ comes into focus. The AnTZ is rarely viewed in its entirety in one field of view. Adjusting and re-angling the anoscope as well as using cotton swabs to manipulate the folds, hemorrhoids, or prolapsing mucosa will allow all aspects of the AnTZ to be viewed (Fig. 99-7).
- 8. A thorough examination requires reapplication of acetic acid to the entire SCJ multiple times. Not only does the staining of the abnormalities fade, it is essential that all areas, including those between the folds, be stained.
- 9. Lugol's solution may be applied judiciously to help better define lesions or their margins. Normal glycogenated squamous epithelium stains dark mahogany. Abnormal lesions lack glycogen and may stain partially or not at all. Columnar epithelium and scar tissue also will not stain with Lugol's. We also do not use Lugol's solution on the fully keratinized perianal area because the staining patterns are not sensitive enough. It is important to observe directly through the colposcope while the Lugol's solution is

**Figure 99-8** This high-grade anal intraepithelial neoplasia is faintly acetowhite with a mosaic pattern noted in the bottom edge of the lesion.

**Figure 99-9** High-grade anal intraepithelial neoplasia is more clearly delineated with application of Lugol's staining.

- applied to differentiate areas not expected to pick up the Lugol's stain from true nonstaining areas that are lesions. Most HGAIN lesions will be Lugol's negative. As much as half of LGAIN lesions also are Lugol's negative. However, lesions that are partially or positively stained with Lugol's solution are rarely HGAIN. As such, choosing a Lugol's-negative lesion to sample may help increase the yield for HGAIN (Figs. 99-8 and 99-9).
- 10. Once the entire AnTZ has been observed, continue the examination of the anal canal as the anoscope is slowly withdrawn. Continue to apply more acetic acid using a scopette or cotton-tipped swabs. Lesions seen at the SCJ may radiate distally into the canal and even to the verge. A complete evaluation includes assessment of the extent of all lesions so that a treatment recommendation can be made.
- 11. Examine the verge and perianal skin applying additional acetic acid. By consensus, the perianal area is considered to radiate 5 cm beyond the verge. Perianal lesions are more difficult to evaluate and may require applying a gauze soaked in 5% acetic acid for 3 to 5 minutes (Fig. 99-10).

#### **Performing Anal Biopsy**

- 1. Biopsies are directed at areas thought to represent the highest grade of abnormality (see Chapter 137, Colposcopic Examination, which reviews colposcopic findings) to determine (1) the severity of the disease present and (2) the extent of involvement in order to determine treatment options. If there are many different lesions, sampling multiple areas will help define the extent of HGAIN or LGAIN to clarify therapeutic options.
- Anal biopsies are smaller than cervical biopsies. Forceps no larger than 2 to 3 mm should be used, such as the baby Tischler or mini-Townsend.
- Insert the forceps through the anoscope while it is closed. Directly visualize the area for biopsy to determine that the correct area is

**Figure 99-10** Perianal high-grade anal intraepithelial neoplasia with acetowhite changes, shallow ulcerations, and hyperpigmentation.

Figure 99-11 Opening the forceps partially is wide enough for an anal specimen and will help minimize bleeding.

being sampled. A *common mistake of novice providers* is to look around instead of through the colposcope to visualize the lesion during biopsy.

- 4. Sample lower lesions first so bleeding does not obscure other lesions (which can happen if superior lesions are sampled first).
- 5. When the lesion is visualized, adjust the forceps so it is partially open and adjacent to the lesion. A partially opened forceps will provide an adequate specimen and only minimal bleeding. Open it in the direction that allows the forceps to grasp the tissue most easily. For some lesions the forceps must be positioned sideways or upside down (Fig. 99-11).
- 6. The normal pressure of the anus after removing the anoscope is often sufficient to stop bleeding, but a small amount of Monsel's solution can be applied to promote hemostasis. Do not use Monsel's solution until all biopsies are complete because it can interfere with the pathology reading.
- 7. HRA-directed biopsy is a "one-handed" procedure because one hand will always be holding the anoscope. It takes practice to adeptly manipulate the specimens into the formalin containers with one hand while holding the anoscope in place for the remainder of the procedure. If available, an assistant can place biopsy specimens in containers.
- 8. Anal biopsies do not require anesthesia. Perianal biopsies, however, are similar to vulvar biopsies and require a small amount of injectable 1% lidocaine with epinephrine. Buffering the lidocaine with sodium bicarbonate (2 mL NaHCO<sub>3</sub>:10 mL lidocaine) improves the comfort of the procedure.

#### **High-Resolution Anoscopy Observations**

- Squamous epithelium usually appears lighter and pinker compared with columnar or rectal epithelium, which is darker and redder. In most people, the anoscope is longer than the anal canal and, if inserted fully, the colonic mucosa will be noted first as the obturator is removed.
- 2. The anal canal of most women is shorter compared with men. The AnTZ is much closer to the verge in some women and it may seem as if the anoscope is nearly outside before the AnTZ is viewed. In people with anal prolapse, the AnTZ may also be

- noted at the verge or at times seen externally. Those who have had surgery may also present with the SCJ closer to the verge. Acetic acid is still helpful in delineating the AnTZ and SCJ.
- 3. If the AnTZ does not appear readily, generously apply acetic acid while manipulating the anoscope. Eventually a thin white line should begin to appear. Once an area of the AnTZ has been located, the remainder should be visible with manipulation of the anoscope and continued application of acetic acid.
- 4. Clinical/colposcopic terminology for describing anal lesions is similar to that for cervical lesions. Lesions are described by color (acetowhite), contour (raised or flat), surface vascularity (punctation, mosaic patterns, atypical vessels), margins (distinct and indistinct), and Lugol's staining (negative, partial, positive). Lesion margins are not very well defined in anal mucosa. Frequently one or more parts of the lesion margins are not observed, especially adjacent to the columnar epithelium.
- Lesions appear as demarcated acetowhite areas with characteristics similar to those seen on the cervix. Refer to the Chapter 137, Colposcopic Examination, for a more thorough discussion of lesion characteristics.
- 6. A typical raised LGAIN lesion is acetowhite and raised, has warty, looped capillary vessels and papillae, and is often partially stained with Lugol's solution. A typical HGAIN lesion is acetowhite and flat, has punctation and mosaic patterns, and is Lugol's negative (Table 99-1 and Figs. 99-12 and 99-13).
- 7. Be consistent when describing the location of the lesions. The anal "clock" is different from the cervical "clock." By convention, the 12:00 position is posterior in the anus if the patient is standing and bent over a table, but anterior if in the lithotomy position. Because referrals are frequently made to colorectal surgeons it is helpful to provide the locations anatomically (posterior, anterior, left or right lateral; Fig. 99-14).

#### **COMMON ERRORS**

- Applying lubricant or doing a digital examination before obtaining cytology
- Not sampling the entire AnTZ when obtaining cytology
- Not being persistent and examining the entire AnTZ with the colposcope
- Looking around (not through) the colposcope when obtaining biopsies
- Obtaining too large a sample for biopsy, causing excessive bleeding

#### INTERPRETATION OF RESULTS

Cytology is considered a screening test and is not diagnostic. Diagnosis is based on the histologic result. HGAIN is considered the cancer precursor lesion, and LGAIN is considered a benign abnormal lesion. Results that are described as "atypia suggestive of LGAIN" are considered atypical but not abnormal. "Atypia cannot rule out HGAIN" is also an atypical finding and an indicator for HRA. A higher grade on cytology than the biopsy histologic grade

TABLE 9	99-1 Typical Featur	es of Anal Intraep	oithelial Neoplasia a	and Cancer on High-Resolution	n Anoscopy
	DRE	Surface Characteristics	Epithelial Characteristics	Vascular Characteristics	Lugol's Staining
LGAIN	Granular, soft warty nodularity	Raised or flat	Papillae, micropapillae	Fine or coarse punctation, warty vessels	Negative, partial or complete
HGAIN	Nonpalpable or subtle thickening	Flat or slightly raised	Smooth	Coarse punctation, mosaic patterns, increased vascularity	Negative
Cancer	Firm mass, indurated or distinct thickening	Raised, ulcerated, occasionally flat	Peeling or denuded, heaping edges	Atypical, large, nonbranching vessels, grossly dilated, friable	Negative

DRE, digital rectal examination; HGAIN, high-grade anal intraepithelial neoplasia; LGAIN, low-grade anal intraepithelial neoplasia.

Figure 99-12 Typical low-grade anal intraepithelial neoplasia.

suggests that the lesion was not seen on HRA and the examination may have to be repeated. Repeat HRA examination is indicated if HGAIN was found on cytology but not on biopsy.

Reasons for discordant results include inadequate examinations due to obscuring hemorrhoids or warts (diffuse circumferential warts may obscure smaller areas of HGAIN) or that the highest-grade lesions were missed on HRA because of lack of adequate staining. The learning curve for HRA is steeper than for cervical colposcopy because of differences between anal and cervical anatomy. Discordant results are not unusual for novices and occur even for experienced providers.

A thorough discussion of *treatment* is beyond the purview of this chapter. The threshold for treatment depends on the situation (see Fig. 99-2). LGAIN can be treated when it is symptomatic, when the patient requests it to be removed, and when it is diffuse and obscures the ability to perform an adequate examination. HGAIN should be treated unless the patient is medically fragile or treatment is otherwise contraindicated. These patients should be followed carefully by cytology and digital rectal examination every 3 to 4 months. Most HGAIN can be treated as an office procedure using the infrared coagulator. Diffuse circumferential disease or patients who cannot tolerate long procedures may require referral to a colorectal surgeon for surgical removal or ablation.

Ablation is the mainstay of therapy. Office ablation techniques include cryotherapy (only for external lesions), trichloroacetic acid or bichloroacetic acid for small-volume disease, and electrocautery or infrared coagulation for larger-volume disease. Small lesions can sometimes be excised with the forceps or snipped off using sharp tissue scissors such as Metzenbaums. Laser has been used for both office and surgical ablation but requires a smoke evacuator. In surgery, most patients receive fulguration or electrocautery.

#### **CPT/BILLING CODES**

There is no CPT code for HRA. 46999 is an "unlisted anoscopy code." It can be used to describe intraoperative HRA to guide treatment of anal high-grade squamous intraepithelial lesions, but must

Figure 99-13 Typical high-grade anal intraepithelial neoplasia.

#### Anal clock in the left lateral HRA position

Posterior = 12:00 Anterior = 6:00

R lateral R lateral

Post. Ant. Post. Ant.

L lateral L lateral

Internal External

**Figure 99-14** The "anal clock" from the perspective of the left lateral high-resolution anoscopy (HRA) position. Note that posterior = 12:00 and that this is the opposite of the "cervical clock."

include a letter explaining why it is medically justified. Not dictating a report or sending a letter may delay reimbursement.

46600 Anoscopy Anoscopy with biopsy 46606 46610 Anoscopy with polypectomy 46614 Anoscopy with destruction 46900 Destruction, chemical, simple 46910 Destruction, electro, simple 46916 Destruction, cryosurgical, simple 46922 Destruction, surgical excision 46924 Destruction, extensive lesions

46937 Cryosurgical destruction, benign rectal tumor

For initial visits, or if the patient is referred to you and you send a letter to the referring provider, you can bill for a consultation (99243 or 99244) and also for the anoscopy procedure with or without biopsy (46600 or 46606). This is the only time you can bill for both. Medicare has eliminated consultation codes as of 2010, and other insurances may do the same.

If the patient presents with an additional problem and has anoscopy, you may be able to bill for an established office visit (99213 or 99214 with a -25 modifier and 46600 or 46606), but you must specify using the appropriate ICD-9 code for the additional problem.

Some providers also use the code for transanal excision of rectal tumor when treating lesions that are proximal to the dentate line, but this is somewhat controversial and may be subject to scrutiny.

#### **ICD-9-CM DIAGNOSTIC CODES**

HIV infection
Condyloma
Anal cancer
Benign neoplasm of anus (low-grade squamous intraepithe-lial lesion or AIN 2)
Carcinoma in situ of anal canal (AIN 3)

# **COLONOSCOPY\***

John Bartels Pope

Colonoscopy is a procedure that allows for visual inspection of the entire large bowel from the distal rectum to the cecum. The procedure is generally well accepted by patients and, in the proper hands, is a safe and effective means of examining the large bowel. A well-trained endoscopist can usually perform a total colonoscopy in 30 to 45 minutes, achieving cecal intubation in greater than 90% of attempted procedures under optimal conditions (excellent bowel preparation, high-quality equipment, technical support, appropriate sedation, and low-risk patient population).

Colonoscopy has a greater sensitivity and specificity for the detection of colonic polyps and colorectal cancers (CRCs) than fecal occult blood testing, air-contrast barium enema, or computed tomographic (CT) colonography (virtual colonoscopy), and greater sensitivity than flexible sigmoidoscopy because more of the colon is visualized. Colonoscopy is the procedure of choice in the work-up of most cases of lower gastrointestinal bleeding. A significant advantage of colonoscopy over radiologic evaluation of the large intestine is the ability to perform additional diagnostic and therapeutic measures, such as biopsy, polypectomy, and control of bleeding. Although traditionally performed in the hospital, colonoscopy can also be performed in free-standing offices or in ambulatory endoscopy centers.

It is widely accepted that the vast majority of colon cancers arise from adenomatous (neoplastic) polyps. It has been shown that the removal of adenomatous polyps by colonoscopic polypectomy can reduce the incidence of colorectal cancer by 76% to 90%. Colonoscopy then provides an opportunity to greatly influence the incidence of colorectal cancer by allowing the removal of polyps throughout the entire colon.

#### **ANATOMY**

The colon is approximately 150 cm in length from anal verge to cecum.

#### Anus

• The outlet to the gastrointestinal tract

#### Rectum

- Dentate (pectinate) line demarcating junction between painsensitive squamous epithelium of anus and pain-insensitive columnar epithelium of rectum
- Approximately 15 cm in length with capacious lumen
- Prominent folds (valves of Houston) that may create potential blind spots
- Mucosal transparency with prominent hemorrhoidal venous plexus visible

#### Sigmoid colon

- Variably mobile (key to successful colonoscopy)
- Loops anteriorly, then posteriorly to be retroperitoneal
- 35 to 45 cm in length

#### Descending colon

- Fixed, straight course up left paracolic gutter
- Narrowest portion of colon
- Retroperitoneal
- Approximately 20 to 30 cm in length

#### Transverse colon

- Longer than the distance it traverses and may sag into umbilical region
- Lumen generally has a triangular appearance
- Approximately 45 to 55 cm in length

#### Ascending colon

- Capacious lumen with straight course
- Retroperitoneal into right paracolic gutter
- Terminates at ileocecal valve, which demarcates beginning of cecum
- Approximately 10 to 20 cm in length

#### Cecum

- Variable mobility and capacious lumen
- Landmarks include ileocecal valve, appendiceal orifice, and terminal portion of taeniae coli ("crow's foot")
- Transillumination is frequently seen
- Approximately 5 to 8 cm in length

#### **INDICATIONS**

#### **Diagnostic Indications**

- Total colon evaluation after the finding of adenomatous polyps, especially high-risk polyps (i.e., those >1 cm, small polyps with advanced histopathology, or multiple small adenomatous polyps), during flexible sigmoidoscopy.
- Evaluation of abnormal or equivocal barium enema.
- Evaluation of overt or occult colonic or rectal bleeding.
- Evaluation of abnormal findings on CT colonography.
- Evaluation of iron-deficiency anemia of undetermined cause.
- Surveillance of neoplastic disease after removal of polyps or cancer
- Screening for neoplastic disease in patients with family history of colorectal cancer or adenomatous (neoplastic) polyps before age 60 years; screening should begin at 40 years of age or 10 years before the age of discovery in relative.
- Screening and surveillance for neoplastic disease in hereditary cancer syndromes
  - Familial adenomatous polyposis syndrome (FAP). Gene carriers or at-risk family members who have not had genetic testing or are from families in whom the gene test is uninformative should be offered a flexible sigmoidoscopy or colonoscopy every 12 months starting at around 10 to 12 years of age and continuing until 35 to 40 years of age if negative. Colonoscopy is necessary in attenuated FAP, where the usual presentation of thousands of polyps is reduced to less than 100 polyps, which may be more proximally located.

<sup>\*</sup>EDITOR'S NOTE: Much of the information in Chapter 103, Flexible Sigmoidoscopy, is very pertinent to colonoscopy. Material will not be repeated here. The reader is encouraged to review that chapter also.

- Hereditary nonpolyposis colon cancer syndrome (HNPCC). HNPCC is defined as CRC in three or more family members, two of whom are first-degree relatives of the third, with at least two generations involved and at least one person diagnosed with CRC before 50 years of age. Use of the term *nonpolyposis* is a misnomer. Polyps do indeed occur in HNPCC, just not to the extent seen with FAP. Individuals at risk for HNPCC should undergo colonoscopy every 1 to 2 years starting at 20 to 25 years of age or 10 years younger than the age of the earliest diagnosis of cancer in the family, whichever is earlier.
- Evaluation and surveillance of inflammatory bowel disease (after 8 years in pancolitis and after 12 years in left-sided colitis).
- Evaluation of chronic diarrhea of undetermined cause.
- Intraoperative evaluation of polypectomy site, bleeding lesions, or anastomotic leaks.
- Endosonography for local staging (primary tumor, regional nodes, and metastasis [TNM]) of colorectal cancer.
- Screening in average-risk population (>50 years of age) and in the increased-risk groups (Table 100-1).
- Evaluation of significant weight loss.
- Evaluation of abdominal pain.

**NOTE:** Colonoscopy is often of little benefit in determining the causes of chronic lower abdominal pain or changes in bowel habits in the absence of rectal bleeding, weight loss, or anorexia.

#### Therapeutic Indications

- Biopsy of suspect lesion
- Polypectomy
- Therapy of bleeding lesions
- Removal of foreign body
- Reduction of sigmoid volvulus
- Decompression of pseudo-obstruction of colon
- Dilation of colonic strictures and placement of colonic stents
- Laser therapy of lesions

#### **CONTRAINDICATIONS**

#### **Absolute**

- Acute abdomen
- Suspected peritonitis
- Acute diverticulitis with systemic symptoms
- Acute exacerbation of inflammatory bowel disease
- Documented or suspected bowel perforation
- Patient refusal
- Risk to patient outweighs benefits of procedure

#### **Relative**

- Unstable cardiopulmonary status
- Recent myocardial infarction or pulmonary embolism

- Significant pelvic or abdominal adhesions
- Blood coagulation abnormalities
- Recent (within 1 week) bowel surgery
- Hyperplastic polyps on flexible sigmoidoscopy with no other indication
- Poorly prepared patient
- Uncooperative patient
- Metastatic adenocarcinoma of unknown primary site in the absence of colonic symptoms when it will not influence management
- Severe neutropenia
- Pregnancy (second or third trimester)
- Large abdominal aortic aneurysm
- Splenomegaly

#### **EQUIPMENT**

Basic equipment necessary to perform colonoscopy includes the following:

- Fiberoptic colonoscope
- Light source (i.e., halogen or xenon)
- Suction apparatus
- Biopsy forceps
- Polypectomy snares
- Electrosurgical unit
- Conscious sedation setup (see Chapter 2, Procedural Sedation and Analgesia)

Additional instruments that may also be useful include injection needle catheter, heater probe or multipolar cautery probe, polyp retrieval baskets, endoscopic clips, and three-prong grasping forceps. Lubricating jelly, gauze pads, saline, sterile water, protective gowns, and protective eyewear are also recommended.

The *colonoscope* is similar in design to the sigmoidoscope, only longer. The outside diameter of the insertion tube varies from 11 to 13 mm, and the length of the shaft varies from 105 to 185 cm. The narrower scopes are typically used in pediatric settings and are generally lighter with a more flexible shaft. The scopes have an eyepiece with focusing controls; control wheels to deflect the tip through a range of positions, including deflection over 180 degrees; a biopsy port; suction and air and water control knobs; and locking levers to fix control wheels in a particular position (see Chapter 103, Flexible Sigmoidoscopy).

Most colonoscopies are now performed with video endoscopes. Videoscopes are fiberoptic devices; however, they use a charge-coupled device to convert light energy into electronic signals that can be converted by a computer processor into images. Videoscopes provide recording capability of entire procedures, and they also allow transmission of images to remote sites. Videoscopes also provide for a more comfortable posture for the endoscopist during the procedure. The newest video colonoscopes offer optional features such as variable stiffness capability, forward water jet,

# TABLE 100-1 Guidelines for Screening and Surveillance for the Early Detection of Colorectal Adenomas and Cancer in Individuals at Increased Risk or at High Risk

Risk Category	Age to Begin	Recommendation	Comment
Increased Risk—Patients wi	th History of Polyps at Prior	Colonoscopy	
Patients with small rectal hyperplastic polyps	_ ` ` ` ` ` ` ` ` ` ` ` ` ` ` ` ` ` ` `	Colonoscopy or other screening options at intervals recommended for average-risk individuals	An exception is patients with a hyperplastic polyposis syndrome. They are at increased risk for adenomas and colorectal cancer and need to be identified for more intensive follow-up.
Patients with 1 or 2 small tubular adenomas with low- grade dysplasia	5 to 10 years after the initial polypectomy	Colonoscopy	The precise timing within this interval should be based on other clinical factors (such as prior colonoscopy findings, family history, and the preferences of the patient and judgment of the physician).

# **TABLE 100-1** Guidelines for Screening and Surveillance for the Early Detection of Colorectal Adenomas and Cancer in Individuals at Increased Risk or at High Risk—Cont.

Risk Category	Age to Begin	Recommendation	Comment
Patients with 3 to 10 adenomas or 1 adenoma >1 cm or any adenoma with villous features or high- grade dysplasia	3 years after the initial polypectomy	Colonoscopy	Adenomas must have been completely removed. If the follow-up colonoscopy is normal or shows only 1 or 2 small, tubular adenomas with low-grade dysplasia, then the interval for the subsequent examination should be 5 years.
Patients with >10 adenomas on a single examination	<3 years after the initial polypectomy	Colonoscopy	Consider the possibility of an underlying familial syndrome.
Patients with sessile adenomas that are removed piecemeal	2 to 6 months to verify complete removal	Colonoscopy	Once complete removal has been established, subsequent surveillance needs to be individualized based on the endoscopist's judgment. Completeness of removal should be based on both endoscopic and pathologic assessments.
Increased Risk—Patients with			
Patients with colon and rectal cancer should undergo high-quality perioperative clearing	3 to 6 months after cancer resection, if no unresectable metastases are found during surgery; alternatively, colonoscopy can be performed intraoperatively	Colonoscopy	In the case of nonobstructing tumors, this can be done by preoperative colonoscopy. In the case of obstructing colon cancers, CTC with intravenous contrast or DCBE can be used to detect neoplasms in the proximal colon.
Patients undergoing curative resection for colon or rectal cancer	I year after the resection (or I year following the performance of the colonoscopy that was performed to clear the colon of synchronous disease)	Colonoscopy	This colonoscopy at I year is in addition to the perioperative colonoscopy for synchronous turnors. If the examination performed at I year is normal, then the interval before the next subsequent examination should be 3 years. If that colonoscopy is normal, then the interval before the next subsequent examination should be 5 years. Following the examination at I year, the intervals before subsequent examinations may be shortened if there is evidence of HNPCC or if adenoma findings warrant earlier colonoscopy. Periodic examination of the rectum for the purpose of identifying local recurrence, usually performed at 3- to 6-month intervals for the first 2 or 3 years, may be considered after low-anterior resection of rectal cancer.
Increased Risk—Patients win Either colorectal cancer or	Age 40 years or 10 years	Colonoscopy	Every 5 years
adenomatous polyps in a first-degree relative before age 60 years or in 2 or more first-degree relatives at any age	before the youngest case in the immediate family		
Either colorectal cancer or adenomatous polyps in a first-degree relative ≥age 60 years or in 2 second-degree relatives with colorectal cancer	Age 40 years	Screening options at intervals recommended for average-risk individuals	Screening should begin at an earlier age, but individuals may choose to be screened with any recommended form of testing.
High Risk			
Genetic diagnosis of FAP or suspected FAP without genetic testing evidence	Age 10 to 12 years	Annual FSIG to determine if the individual is expressing the genetic abnormality and counseling to consider genetic testing	If the genetic test is positive, colectomy should be considered.
Genetic or clinical diagnosis of HNPCC or individuals at increased risk of HNPCC	Age 20 to 25 years or 10 years before the youngest case in the immediate family	Colonoscopy every 1 to 2 years and counseling to consider genetic testing	Genetic testing for HNPCC should be offered to first-degree relatives of persons with a known inherited MMR gene mutation. It should also be offered when the family mutation is not already known, but 1 of the first 3 of the modified Bethesda Criteria is present.
Inflammatory bowel disease, chronic ulcerative colitis, and Crohn's colitis	Cancer risk begins to be significant 8 years after the onset of pancolitis or 12 to 15 years after the onset of left-sided colitis	Colonoscopy with biopsies for dysplasia	Every I to 2 years; these patients are best referred to a center with experience in the surveillance and management of inflammatory bowel disease

CTC, Computed tomographic colonography; DCBE, double-contrast barium enema; FAP, family adenomatous polyposis; FSIG, flexible sigmoidoscopy; HNPCC, hereditary nonpolyposis colon cancer; MMR, mismatch repair.

From Levin B, Lieberman DA, McFarland B, et al: Screening and surveillance for the early detection of colorectal cancer and adenomatous polyps, 2008: A joint guide-line for the American Cancer Society, the US Multi-Society Task Force on Colorectal Cancer, and the American College of Radiology. CA Cancer J Clin 58:130–160, 2008. Copyright 2008 American Cancer Society.

high-resolution HDTV imaging, narrow-band imaging, close focusing, and 170-degree field of view. Video endoscopy setups are significantly more expensive than conventional setups.

Cleaning and disinfecting the instrument and equipment are very important to prevent iatrogenic infections. Strict adherence to appropriate cleaning protocols virtually eliminates these risks. The American Society for Gastrointestinal Endoscopy (ASGE) provides practice guidelines for infection control during gastrointestinal endoscopy. Company representatives also provide excellent guidelines and videotapes demonstrating the process.

#### PREPROCEDURE PATIENT PREPARATION

Informed consent is a necessary component of colonoscopy. Consent should be obtained by the physician and should include discussion of the nature of the procedure (how it is performed), expected benefits of the procedure, risks of the procedure (including those from sedation, procedure complications [perforation and bleeding], and the possibility of missed lesions), and alternatives to the procedure. The consent process may be facilitated with the use of patient education videotapes or written materials available from various organizations (e.g., ASGE, Society of American Gastrointestinal Endoscopic Surgeons, and The National Procedures Institute). Sample consent forms and patient education handouts are also available online at http://drpearlman.btrtest.com/patient\_education.htm and http://springfieldasc.com/patient-information/patient-forms.

A focused history should be obtained before the procedure to ensure that an appropriate indication exists for the procedure and to identify factors that may influence safe and effective performance of the procedure and subsequent management of the patient. Pertinent history should include present illness, past medical and surgical history (hysterectomy or abdominal surgeries may increase intubation difficulty), current medications, allergies, and tobacco and alcohol use. The patient should also be asked about any previous complications from anesthesia, as well as any history of coagulation abnormalities or chronic use of narcotics or tranquilizers, which may influence the ability to properly sedate (Fig. 100-1).

Physical examination should include (as a minimum) assessment of vital signs and sensorium and heart, lung, and abdominal examination.

Laboratory testing is not routinely performed before colonoscopy; however, in specific circumstances testing may be warranted (e.g., severe anemia with anticipation of polypectomy, known fluid and electrolyte abnormality, anticoagulation).

A clean bowel is essential for colonoscopy. Two of the most common and effective *preparations for cleansing the bowel* include the following:

- 1. Polyethylene glycol (PEG) solution (4 L) taken orally (Colyte, GoLYTELY) over a 1- to 3-hour period
- Magnesium citrate solution (10 oz) taken with four bisacodyl tablets (5 mg) the afternoon before the procedure, and repeat the magnesium citrate the morning of the procedure

Although commonly used in the past as a bowel preparation agent, aqueous phosphosoda (NaP) colon preparations (e.g., Fleet) are no longer approved for that purpose by the U.S. Food and Drug Administration because of the risk of renal toxicity and renal failure. The over-the-counter Fleet preparation is no longer manufactured. Tablet formulations of NaP (Visicol, Osmoprep) are available by prescription but now carry a black-box warning. Caution should be used when administering any phosphosoda-type preparation to patients with renal insufficiency, ascites, or congestive heart failure. Acute renal failure has been reported with these preparations. The use of NaP preparations is declining, and future use should probably be avoided in light of the current restrictions and risk.

Polyethylene glycol bowel preparations should be administered starting at 4 PM the day before colonoscopy. After beginning the preparation the patient can have only clear liquids until midnight,

then NPO. One or two tap water enemas administered 1 or 2 hours before the procedure may also be helpful if particulate matter or dark-colored bowel contents are still present. In general, enemas should be avoided because they are unpleasant for the patient and may cause punctate erosions/inflammation in the colonic mucosa, falsely suggesting colon pathology. This phenomenon can also be seen when NaP preparations are used.

It is important for the clinician to individualize the preparation for each patient and to take time to explain the reasons for the bowel cleansing preparation. If patients are chronically dependent on laxatives or have had a previous inadequate bowel preparation, it may be advisable to add an additional day of clear liquids before beginning the preparation. Optimal examination may be better accomplished if the patient has received a PEG solution (i.e., GoLYTELY, NuLYTELY, Colyte); however, many physicians claim "less is best." PEG solutions may be more palatable when taken chilled or mixed with a sugar-free drink mix (red-colored mixes should be avoided). Smallervolume PEG-type preparations (e.g., Half-Lytely) are now available that reduce the volume necessary for the patient to consume and add a mild laxative agent to the process. A less expensive, bettertasting alternative preparation combines 238 g of over-the-counter PEG laxative (MiraLax powder) with 0.5 gallon of Gatorade or similar drink that is consumed over 1 to 2 hours. Four bisacodyl tablets are taken about 2 hours before drinking the preparation the afternoon before the procedure.

It is important to maintain adequate hydration of the patient before, during, and after the administration of any colon preparation to minimize possible adverse events. This is especially important in older individuals and in those with known renal disease or who are on medications that may predispose to fluid and electrolyte disturbances.

Diabetic patients will be NPO for an extended time during the colon preparation and should generally refrain from taking their diabetes medications beginning the day of the preparation. It also is advisable to withhold iron therapy beginning 4 to 5 days before the preparation because iron tends to darken and thicken the stool, thereby decreasing preparation effectiveness.

Bowel cleansing is essential, not only to provide an unobstructed view but to minimize the rare, but possible, risk of combustion from methane gas should cautery be used during polypectomy or to stop bleeding. Good bowel preparation may also help improve surgical outcomes in the case of perforation and subsequent repair.

#### **ANTIBIOTIC PROPHYLAXIS**

The American Heart Association, American College of Cardiology, and the Standards of Training and Practice Committee of the ASGE have recently updated their recommendations regarding antibiotic prophylaxis for prevention of bacterial endocarditis. Both groups no longer recommend periprocedural antibiotic prophylaxis for the prevention of infective endocarditis for any gastrointestinal endoscopic procedure, regardless of the patient's cardiac risk status. When used, antibiotic prophylaxis regimens usually include ampicillin and gentamicin, or vancomycin in penicillin-allergic patients.

#### **ANTICOAGULATION**

The Standards of Practice Committee of the ASGE has developed practice guidelines for the use of colonoscopy in conjunction with anticoagulated patients. Management is determined by establishing risk of bleeding versus risk of thromboembolic events. Colonoscopy with polypectomy is considered a high-risk procedure for bleeding. Conditions considered high risk for thromboembolic events are chronic atrial fibrillation with associated valvular heart disease, mechanical valve in the mitral position, and mechanical valve and prior thromboembolic event. High-risk procedures (i.e., colonoscopy with polypectomy) performed in high-risk conditions should be managed by discontinuing warfarin 3 to 5 days before the procedure. Consider heparin while

the international normalized ratio (INR) is below the therapeutic level. Low-risk conditions require only discontinuation of warfarin 3 to 5 days before the procedure without use of heparin. The ASGE no longer considers recent aspirin or nonsteroidal anti-inflammatory drug use a contraindication to colonoscopy with polypectomy in the absence of a preexisting bleeding disorder.

An alternative is to use "bridge anticoagulation" with low-molecular-weight heparin. Although low-molecular-weight heparin bridging is being used more frequently, prospective, controlled data supporting this method are currently lacking.

#### **SEDATION**

Most colonoscopic examinations are performed while the patient is under conscious sedation (see Chapter 2, Procedural Sedation and Analgesia), although *unsedated colonoscopy is possible* in some circumstances with motivated patients. Sedation may allow for a more thorough examination of the colon because of increased patient comfort and decreased anxiety. Appropriate equipment must be available to monitor blood pressure, pulse, and respiration. A pulse oximeter is now commonly used to monitor oxygen saturation as well. During colonoscopy, it is mandatory to have an assistant available to monitor the patient. Intravenous (IV) access should be established and maintained during the entire procedure in patients receiving IV sedation.

Benzodiazepines are the drugs most commonly used for sedation and include *midazolam* (*Versed*) 2 to 5 mg or *diazepam* (*Valium*) 5 to 10 mg. *Meperidine* (*Demerol*) 25 to 100 mg or *fentanyl* (*Sublimaze*) 25 to 100 µg is often used in conjunction with benzodiazepines to achieve optimal sedation. These medications should be administered slowly through the IV route. Dangerous side effects can be reversed with *flumazenil* (*Romazicon*) or *naloxone* (*Narcan*), although properly titrating these medications will minimize the need for these drugs. *Propofol* (*Diprivan*) given as repeated boluses (10 to 20 mg) IV is becoming more commonly used as a sedation agent in colonoscopy because of its rapid, profound sedative effect and subsequent clearance, with faster patient recovery time. Endoscopists should be thoroughly familiar with the pharmacology of all these drugs. Further discussion is found in Chapter 101, Esophagogastroduodenoscopy, and Chapter 2, Procedural Sedation and Analgesia.

A "crash cart" should be immediately available in case of cardiopulmonary arrest. See Chapter 220, Anaphylaxis, and the discussion regarding Banyan kits for the office.

#### **TECHNIQUE**

#### Colonoscopy

The procedure for colonoscopy is as follows (also see Chapter 103, Flexible Sigmoidoscopy, because the technique is virtually identical for the first 70 cm):

- 1. Place the patient on the examining table in the *left lateral decubitus position*.
- 2. Check all of the equipment for proper functioning.
- 3. After appropriately sedating the patient, perform a *digital anorectal examination* with a well-lubricated, gloved examining finger.
- 4. Lubricate the shaft of the colonoscope and gently insert its tip into the anal canal. The lumen of the bowel should be directly visualized at all times during the colonoscopy procedure.
- 5. *Insufflate air* into the *rectum* until the lumen becomes readily apparent. The three "valves" of Houston (i.e., prominent mucosal folds) are often seen as consistent landmarks. The plexus of blood vessels is usually very apparent in the rectal mucosa (Fig. 100-2). The scope can usually be advanced without difficulty as far as the rectosigmoid junction at 15 to 18 cm.
- Enter the sigmoid colon by passing the scope through the rectosigmoid angle. The sigmoid colon is the most common site of difficulty in passage of the instrument. There may be fixation of

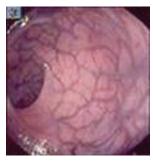

Figure 100-2 Endoscopic view of hemorrhoidal plexus of blood vessels in normal rectum mucosa.

the bowel from diverticular disease or adhesions from prior surgery, including a hysterectomy. The sigmoid colon is the most common site of perforation during colonoscopy. Successful passage through the sigmoid colon may require a series of maneuvers including torquing to the right and withdrawing the scope to reduce loops, applying abdominal pressure, repositioning the patient (even into a supine position), or deflating the lumen of excess air. An essential but difficult lesson to learn is that when passage of the scope is impeded, torque the shaft to the right and withdraw the scope to straighten out the bowel. Although intubation should optimally occur while the lumen is being visualized, occasionally a "slide-by" technique is used to negotiate abrupt angulations in the bowel. In these acute turns the lumen cannot be well visualized without extreme deflection of the scope tip. Exaggerated deflections of the scope tip may provide complete views of the lumen, but they often impair forward intubation. In the "slide-by" technique, the lumen view is partially sacrificed to allow the scope to be gently advanced while the mucosa is seen to slide past the scope tip. The endoscopic view of the mucosa appears reddish from the underlying vasculature. A blanching of the mucosa could indicate excessive pressure against the bowel wall, and further insertion should be discontinued as the bowel is straightened using other techniques described previously. Although most endoscopists use the slideby technique occasionally, it should not characterize the intubation technique.

7. The *descending colon* can be recognized by a relatively straight passage through the circular-shaped bowel (Fig. 100-3) to the *splenic flexure*. Traversing the angle of the splenic flexure may resemble passage through the rectosigmoid junction because this angle may be abrupt and may require a small degree of slide-by for passage. The *transverse colon* can be recognized by its characteristic triangular appearance (Fig. 100-4), and it generally has a fairly straight configuration. The *hepatic flexure* is often recognizable by the "liver shadow" (Fig. 100-5), which appears as a bluish-brown area where the liver is in direct

Figure 100-3 Endoscopic view of descending colon.

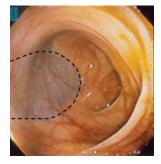

Figure 100-4 Endoscopic view of transverse colon.

contact with the bowel wall. The hepatic flexure is seen as another angle to traverse with the scope. The *ascending colon* may also appear triangular.

- 8. Advance the scope into the *cecum* by pulling back, keeping the tip of the scope in the center of the lumen, and applying full suction to pull the cecum toward the scope tip. The cecal landmarks, which may or may not be prominent, include the *ileocecal valve* (Fig. 100-6) and the *appendiceal orifice* (Fig. 100-7). Convergence of the terminal portion of the taenia coli in the cecum forms a characteristic appearance known as the "crow's foot" or cecal strap (see Fig. 100-6). Other methods to ascertain if the cecum has been reached are to check for ballottement externally above the right inguinal canal or for transillumination in the right lower quadrant (less consistent findings).
- 9. Intubate the terminal ileum by advancing the tip just beyond the ileocecal valve and then deflecting the tip toward the valve as the scope is carefully withdrawn. As the tip of the scope meets the valve opening, torque the scope gently clockwise to allow the tip to advance briefly into the terminal ileum.
- 10. Carefully inspect the colon wall as the scope is withdrawn. Use a circular motion of the tip to inspect behind every mucosal fold. Lavage with water any areas of the bowel with inadequate preparation and carefully reinspect. Obtain any necessary biopsy specimens and remove polyps during this portion of the procedure.

Endoscopists use various combinations of the techniques described in the foregoing discussion in a time-efficient manner to safely intubate the colon to the cecum in a high percentage of cases. It is important to recognize that not every colonoscopy can safely be completed to the cecum. Most colonoscopies take an average of 30 to 45 minutes, although this is variable. Time spent examining the colon during withdrawal may be a more important indicator of quality than overall procedure time. It has been suggested that withdrawal time should be at least 6

**Figure 100-5** Endoscopic view of hepatic flexure. The characteristic liver shadow is outlined by the *dashed line*.

Figure 100-6 Endoscopic view of ileocecal valve (small white arrow) and "crow's foot" (large white arrow) in cecum.

minutes because data have shown a lower polyp detection rate when withdrawal time is shorter than this.

11. Inspect the distal rectum and anorectal junction before completely withdrawing the scope. As the tip of the scope passes the dentate line, reinsert the scope approximately 5 to 10 cm while simultaneously rotating both control wheels counterclockwise to completely deflect the tip back upon itself (retroflexion or turnaround maneuver). Torque the shaft to inspect all around the anorectal junction. Alternatively, use an anoscope (Ives' slotted anoscope is recommended) to complete the examination of this area.

General principles for safe and efficient intubation of the colon to the cecum include the following:

- Minimize air insufflation.
- Keep the instrument straight.
- Avoid loop formation (pull back frequently).
- Avoid advancing the scope blindly (i.e., slide-by technique) when at all possible.
- Do not sedate the patient more than is necessary to maintain comfort.

#### **Polypectomy**

Polyps may be sessile (i.e., broad-based polyps) or pedunculated (i.e., with a stalk; Figs. 100-8 and 100-9). Almost all pedunculated polyps and many sessile polyps can be easily removed with the electrocautery snare with a low risk of perforation and bleeding. Risk may be higher in larger polyps and in those located in the right colon. Sessile polyps may also be removed with hot or cold forceps (Fig. 100-10). The patient experiences no pain with polypectomy.

There has been recent attention in the literature to the concept of "flat" or "depressed" polyps. These polyps are not exophytic and may actually lie below the regular surface of the mucosa, often making their detection difficult during colonoscopy. There is concern that these lesions may have a higher likelihood of

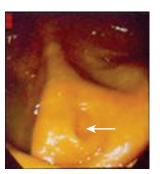

Figure 100-7 Endoscopic view of appendiceal orifice (arrow).

Figure 100-8 Endoscopic view of sessile polyp.

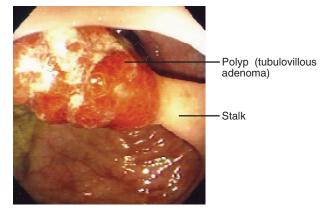

Figure 100-9 Endoscopic view of pedunculated polyp.

malignant degeneration, and yet may go undetected. Careful inspection of the mucosa is imperative as well as insistence on a high-quality bowel preparation to improve early detection of these lesions. Novel techniques are in development that may assist in detection of these lesions, including use of high-magnification colonoscopes with mucosal stains (chromoscopy) and narrow-band imaging.

Biopsies of mucosal lesions are commonly obtained during colonoscopy as well as from normal-appearing mucosa when indicated. Generally, 4 to 6 biopsy specimens should be obtained of mucosal abnormalities and 8 to 10 biopsy specimens should be obtained from larger mass lesions. Pathologic interpretation is generally more sensitive if specimens are obtained from the junction of normal and abnormal mucosa. Avoid sampling areas of apparent necrosis or

deep ulceration because these areas tend to provide poorer tissue specimens.

The procedure for polypectomy is as follows:

- 1. Position the scope so that the polyp can be visualized approximately 2 to 3 cm beyond the tip of the colonoscope. Positioning the polyp at the 5 o'clock position where the port for the electrocautery snare exits can be helpful for biopsy and polypectomy.
- 2. Under direct vision at all times, pass the electrocautery snare catheter through the colonoscope port. Position the tip of the sheath of the snare near the polyp, advance the wire loop, and open it, always under direct vision. Manipulate the snare and maneuver the tip of the colonoscope to place the snare around the polyp. Slowly secure the wire loop around the pedicle or polyp base as the snare catheter is advanced toward the stalk to avoid excessive pull on the stalk or a tangential cut. Maneuver the colonoscope to draw the polyp and snare away from the bowel wall to avoid excess burn injury and possible perforation.
- 3. Apply the electrocautery current (coagulation only) until a white eschar forms around the polyp stalk. Use the least amount of current necessary to achieve the eschar in 2 to 3 seconds (amount varies with the diameter of the stalk and with each electrocautery unit, but generally set at 10 to 15 W). Tighten the snare as coagulation continues until the stalk is transected.
- 4. Retrieve the excised polyp using suction or forceps, or simply regrasp the polyp with the snare. At times this may require removal and reinsertion of the entire colonoscope. Unretrieved polyps may occasionally need to be retrieved later by straining stools after further bowel preparation solutions and cathartics are given, although recovery of polyps using this method is often unsuccessful. Large polyps may require multiple snare-resection excisions. Tissue desiccation without prior biopsy should be avoided because it is very important to have pathologic diagnosis of all colonic lesions.
- 5. Cancerous polyps do not need further resections if the tumor is well differentiated, if there is no lymphatic or vascular invasion, and if there is at least 2 mm between the tumor and the line of resection. With an obvious advanced colon cancer that is friable or ulcerated, biopsies will usually provide sufficient tissue for diagnosis. However, because only tiny samples can be obtained, the cancer may occasionally be missed and the specimens reveal only benign adenomatous tissue. If a strong clinical suspicion of cancer exists, the lesion should be reexamined and resampled. Surgical consultation may be warranted.

#### **OPERATIVE REPORT**

A well-documented procedure note is essential. Notes can be dictated (Fig. 100-11) or hand-written on standardized endoscopy forms (Fig. 100-12). Endoscopy report templates are available for

**Figure 100-10 A,** Polyp being snared. **B,** Polyp being removed with cold forceps.

Procedure: Colonoscopy

Equipment: Olympus Colonoscope

Pre-op diagnosis: History of previous colon polyps

Post-op diagnosis: Diminutive polyp

Endoscopist: Assistant:

#### HPI:

Patient is a 71-year-old African-American male who was seen by Dr. Smith on 6-26-2001 and scheduled for screening colonoscopy. The patient was asymptomatic at the time. The patient had a history of colonic polyps dating back to 1996. The patient was found on that colonoscopy to have a colonic polyp reported as an adenoma by pathology report. Patient was recommended at that time to have a repeat colonoscopy in one year. The patient denied any history of colon cancer. Patient had no iron-deficiency anemia. Patient received one gallon of GoLYTELY yesterday, and the patient was NPO for the procedure today.

Informed consent was obtained from the patient after a full discussion of the risks, benefits and alternatives to the procedure. Patient was also advised of the risk of missed lesions with this procedure. He expressed an understanding of these issues and desired to continue with the colonoscopy. All questions were answered.

**Medications:** Conscious sedation was obtained with 50 mg of Demerol IV push with Versed 1 mg IV push. Conscious sedation was maintained throughout the procedure.

**Procedure:** After conscious sedation was obtained, the patient was placed in the left lateral position. Digital rectal examination was performed, which showed normal sphincter tone, no masses, no external hemorrhoids. Prostate gland was not enlarged. After rectal examination was performed, the regular colonoscope was introduced via the anus and advanced inside the colon into the cecum. The procedure was difficult as a result of redundancies of the colon. External compressions of the abdomen and multiple changes in the position of the patient were required throughout the procedure in order to advance into the cecum. The bowel preparation was adequate. The extent of the exam was to the cecum. The cecum was identified by the ileal-cecal valve, and the appendiceal orifice was clearly visualized. After reaching the cecum, the scope was slowly withdrawn with careful inspection of all aspects of the colon in a circular fashion. Retroflexion was performed inside the rectum before completely straightening the scope, and the scope was subsequently removed from the patient. Patient was transported to recovery area and monitored for 30 minutes until return to baseline state was observed.

Complications: None

**Findings:** There was a diminutive polyp approximately 3 mm in size in the ascending colon that was removed with cold-force biopsy forceps. The colonic mucosa was otherwise normal. Neither diverticula nor internal hemorrhoids were seen.

Impression: Diminutive polyp

**Recommendation:** Given the small size of this polyp and patient's previous history, I would recommend that the patient repeat colonoscopy in 5-10 years. Other methods of colon cancer screening would not be necessary over this 10-year period (i.e., no need for checking fecal occult blood test). Patient will return to the primary care doctor for follow-up, and I have ordered Metamucil, 1 Tbsp mixed with a glass of water once a day for constipation. This can be increased to twice a day if needed.

Figure 100-11 Sample procedure note for colonoscopy.

use with electronic medical records. Procedure notes should include clear recommendations for future management and surveillance of the patient, and this information should be imparted to the referring clinician and the patient.

## **COMMON ERRORS**

- Failure to properly insufflate the colon with air
- Failure to identify landmarks
- Failure to monitor the patient during and after the procedure
- Failure to terminate the procedure when appropriate (lack of progression despite optimal technique, patient instability or intolerance, or risk outweighs benefit)
- Failure to adequately inspect the colonic mucosa

- Failure to straighten the sigmoid loop during insertion
- Failure to ensure an adequate preparation

## **COMPLICATIONS**

Complications occur infrequently with diagnostic colonoscopy and only slightly more frequently with therapeutic colonoscopy. Major complications include the following:

- Cardiopulmonary—over 60% related to sedation and medications used
  - Vasovagal reactions (i.e., hypotension, bradycardia)
  - Arrhythmias (including ventricular tachycardia and fibrillation)
  - Myocardial infarction

Figure 100-12 Sample procedure form for colonoscopy.

- Colon perforation
- Postpolypectomy bleeding
- Postpolypectomy syndrome
- Missed lesions
- Painful experience for patient

Other rare complications include the following:

- Preparation complications
  - Aspiration
  - Dehydration
  - Hyperphosphatemia, hyponatremia
  - Toxic megacolon
  - Renal failure

- Infections without perforation
  - Bacteremia
  - Scope transmission of infectious agent
- Sigmoid or cecal volvulus
- Splenic rupture
- Pancreatitis
- Diverticulitis
- Incarcerated snare or colonoscope

Perforation of the colon occurs at a rate of 0.1% to 0.8% (approximately) for diagnostic colonoscopy and 0.3% to 3% for therapeutic colonoscopy. Perforations can occur for a number of reasons but are most commonly caused by excessive force of insertion of the endoscope tip or with the side of the scope during slide-by, loop

formation, loop reduction, or advancement despite presence of fixating lesions. Other causes of perforation include rupture of diverticulum, rupture of stricture site, transmural injury with electrocautery current with subsequent perforation, or polypectomy- and biopsyinduced perforations. Perforations may also rarely occur from pneumatic rupture of the proximal colon.

Perforations are more common with patients who are oversedated or who are under general anesthesia. It is uncommon for the scope tip to actually penetrate the bowel, but this type of perforation is usually noticed immediately. More frequently the perforation is small and occurs away from the scope tip. It may go unrecognized until the patient later experiences abdominal pain, fever, and distention. A radiographic film of the abdomen or chest will show pneumoperitoneum. In the majority of perforations, immediate surgery is indicated. With fecal soiling a diverting colostomy is needed; however, in the absence of obvious contamination, primary closure may be sufficient. Perforation can occur even in experienced hands and does not per se imply negligence on the part of the endoscopist.

Bleeding postcolonoscopy and postpolypectomy occurs in approximately 1 in 1000 procedures. Bleeding may occur immediately or up to 4 weeks postprocedure. Most cases of bleeding resolve spontaneously, but some may require repeat colonoscopy with attempts to coagulate the area (i.e., epinephrine injection followed by multipolar cautery or heater probe) or laparotomy. Avoiding aspirin prophylaxis for 10 days postpolypectomy may decrease late bleeding risk.

Postpolypectomy syndrome is caused by a transmural thermal injury (i.e., burn) resulting in full-thickness bowel necrosis, which may lead to serosal inflammation. Postpolypectomy syndrome may be accompanied by fever, leukocytosis, and localized and rebound tenderness over the polypectomy site without evidence of intraperitoneal air. A conservative approach generally leads to a good outcome.

Missed neoplastic lesions have been shown to occur even with "expert" endoscopists. In one study, colonoscopy detected 95% of all lesions present. Of the 5% missed, half were not appreciated because of inability to pass the scope far enough; however, in the other half, lesions were passed without being seen. Other studies report a miss rate for advanced lesions (>1 cm) of 12% to 17% for skilled colonoscopists using CT colonography as a reference standard (Pickhardt and colleagues, 2004; Van Gelder and colleagues, 2004).

## POSTPROCEDURE MANAGEMENT

After colonoscopy, monitor the patient (i.e., clinical assessment, blood pressure, pulse, oxygen saturation) for at least 30 minutes and until a return to baseline cognitive function has occurred. Explain the results of the procedure to the patient, including the treatment plan and follow-up appointments. Patients may resume a normal diet on discharge even when polypectomy has been performed. Clearly explain precautions concerning possible delayed bleeding or unrecognized perforation when clinically indicated. Patents should be cautioned not to drive, operate heavy machinery, or sign legal documents for 24 hours after conscious sedation.

# INTERPRETATION AND FOLLOW-UP OF RESULTS

Table 100-2 explains the current recommendations for follow-up of polyps. Pathology results should be communicated to the patient and the referring clinician, and appropriate follow-up or surveillance should be arranged based on the findings.

## **LEARNING COLONOSCOPY**

For a basic overview of colonoscopy principles and technique, the reader is directed to Raskin and Nord's Colonoscopy: Principles and Techniques, which contains excellent diagrams, photographs, tips,

<b>TABLE 100-2</b>	Surveillance Protocols for History
of Colonic N	eoplasia

Finding	Colonoscopy Interval
Small hyperplastic polyps	I0 yr
I-2 tubular adenomas ( <i cm)<br="">and only low-grade dysplasia</i>	5 yr
>3 adenomas, villous elements, or high-grade dysplasia, or >1 cm	3 yr
> 10 adenomas	Within 3 yr
Large sessile adenomas (especially if removed piecemeal)	2–6 mo
Negative follow-up examination	No earlier than 5 yr
Previous colon cancer	High-quality clearance at or around time of resection followed by colonoscopy at 1 yr, then 3 yr and 5 yr if normal
Previous rectal cancer	Clearance of remainder of colon at time of resection, then colonoscopy at 1 yr and 4 yr after resection, then 5-yr intervals

From Rex DK, Petrini JL, Baron TH, et al: Quality indicators for colonoscopy. Gastrointest Endosc 63(4 Suppl):S16–S28, 2006.

and techniques. Additional information on endoscopic technique is found in Williams' chapter on insertion technique in Waye's Colonoscopy: Principles and Practice. Silverstein and Tytgat's Atlas of Gastrointestinal Endoscopy, Forbes' Atlas of Clinical Gastroenterology, and Wilcox's Atlas of Clinical Gastrointestinal Endoscopy contain excellent photographs of colorectal pathology as well as information on gastrointestinal diseases. Anatomy is thoroughly illustrated in Netter's Gastrointestinal Anatomy and Motility. For an in-depth review of colonoscopic polypectomy, see Chapter 12 in Tytgat and colleagues' Practice of Therapeutic Endoscopy and Chapter 38 of Ginsberg's Clinical Gastrointestinal Endoscopy.

Before attempting to perform colonoscopy, it is useful to become proficient and skilled in flexible fiberoptic sigmoidoscopy. The instrument controls and techniques used for flexible sigmoidoscopy are identical to those used to perform colonoscopy. *Formal (CME) courses* are available to teach colonoscopy concepts, skills, and techniques through the American Academy of Family Physicians (AAFP; phone: 1-800-274-2237), The National Procedures Institute (phone: 1-866-674-2631), and the American Association for Primary Care Endoscopy (phone: 913-906-6000, ext. 6706).

One method often used for obtaining colonoscopy skills in the postresidency environment is to form a teaching relationship with a proficient endoscopist willing to act as a preceptor until adequate proficiency is obtained. Colonoscopy can be mastered without fellowship training. Studies show that high-quality care and complication rates essentially identical to those for fellowshiptrained gastroenterologists can be attained (Hopper and colleagues, 1996; Wilkins and colleagues, 2009), and that physician assistants and nurses may also become qualified to perform colonoscopy (Lieberman and Ghormley, 1992; Lomas, 2009). The AAFP has published a position paper on family physicians performing colonoscopy. It can be found on the organization's website (www.AAFP. org/policy/issues/c-colonoscopyposition.html) and includes guidelines for establishing and maintaining proficiency and suggestions for obtaining privileges in colonoscopy. ASGE videotapes on endoscopy technique can be ordered through ASGE at www.asge.org/ TrainingEducationIndex.aspx?id=410. Free endoscopy technique and pathology videos may be viewed at The DAVE Project—Gastroenterology (see Atlases, under Online Resources).

Endoscopy simulators can be a useful adjunct in basic colonoscopy training, particularly when used before actual experience with colonoscopy in patients. Simulators have improved in haptic (touch) feedback technology and also offer various polypectomy

## Box 100-1. Overview of Colonoscopy Privileges

## From the American Academy of Family Physicians Position Paper

- "It is the position of the American Academy of Family Physicians (AAFP) that clinical privileges should be based on the individual physician's documented training and/or experience, demonstrated abilities and current competence, and not on the physician's specialty."
- More than 1440 family physicians across the United States perform colonoscopy in the hospital setting.
- In the 1998 AAFP Practice Profile Survey, 1163 family physicians reported performing colonoscopy in their offices.
- Twenty-six percent of family practice residencies provide training in colonoscopy.
- "Skills for performing colonoscopy are most often acquired during three years of family practice residency training. Another possible route to acquire colonoscopy skills is through preceptorship with a physician who already has such training and privileges. Established experience in flexible sigmoidoscopy examination is helpful in developing colonoscopy skills."
- "The American Society for Gastrointestinal Endoscopy (ASGE) recommends that physicians perform a minimum of 100 diagnostic colonoscopies and 20 snare polypectomies as a threshold for determining clinical competence. However, this recommendation was based on expert opinion, not scientific data."
- "...the AAFP strongly believes that all medical staff members should realize that there is overlap between specialties, and that no one department has exclusive rights to privileges."
- "A legal opinion on privileges for endoscopy submitted to the AAFP in 1993 stated the following:
  - A. Hospitals and peer review participants risk liability under state law if they base credentialing decisions solely on whether or not a physician has obtained specialty certification.
- B. The Council on Ethical and Judicial Affairs of the AMA has issued the opinion that competitive factors must be disregarded in making decisions about credentials and privileges.

- C. There is no evidence that only board-certified gastroenterologists are qualified to perform endoscopic procedures.
- D. Hospitals violate the Medicare Conditions for Participation if they base credentialing decisions solely on specialty board certification.
- E. Hospitals and peer review participants risk loss of federal and state immunity from liability by basing credentialing decisions solely on whether or not a physician has obtained specialty certification."

## From the American Medical Association Clinical Privileges

Regarding clinical privileges, the 1993 AMA Policy Compendium states, "The accordance and delineation of privileges should be determined on an individual basis, commensurate with an applicant's education, training and experience, and demonstrated current competence." It also states that "in implementing these criteria, each facility should formulate and apply reasonable nondiscriminatory standards for the evaluation of an applicant's credentials, free of anticompetitive intent or purpose."

## From the American Society for Gastrointestinal Endoscopy

- "Competency is the minimum level of skill, knowledge, and/or expertise, attained through training and experience, required to perform a procedure safely and proficiently."
- "Departments often develop criteria for recommending privileges and, not surprisingly, these suggested criteria may vary significantly depending on the particular departmental discipline and whether the department represents mainly generalists or specialists."
- "Highly motivated family physicians or internists can acquire a level of training adequate to perform endoscopic examinations of high quality."

Adapted from Worthington DV: AAFP position paper. Colonoscopy: Procedure skills. Am Fam Physician 62:1177–1182, 2000; American Medical Association: Clinical privileges. In AMA Policy Compendium. Chicago, American Medical Association, 1993; and American Society of Gastrointestinal Endoscopy (ASGE): President's message, October, 1999.

simulations. Simulators are manufactured by the Immersion Corporation (www.immersion.com).

## **OBTAINING HOSPITAL PRIVILEGES**

Most hospitals have credentialing standards regarding colonoscopy privileges. Hospitals vary widely in those standards but generally require a minimum number of procedures and possible proctoring of applicants until competency is established. In general, credentialing becomes more restrictive where a high number of specialists perform colonoscopy in the hospital. It is advisable to carefully document all endoscopy experience and related experience and provide a plan for continued medical education and quality assurance when applying for colonoscopy privileges.

See the AAFP Colonoscopy Position Paper for further information (Box 100-1). For articles that may assist in obtaining colonoscopy privileges, see the bibliography (AMA, 1993; ASGE, 1999; Worthington, 2000). A position paper on endoscopy privileging was recently released by the American Association of Primary Care Endoscopists (AAPCE) and can be accessed at www.AAPCE.org. The AAPCE recommends that 50 colonoscopies be used as a target

number for hospitals requiring a certain number before privileging, which is in accord with surgical society recommendations as well.

## **CPT/BILLING CODES**

45378\* Colonoscopy beyond splenic flexure Colonoscopy with foreign body removal 45379\* 45380\* Colonoscopy with biopsy (single or multiple) Colonoscopy with control of bleeding (any method) 45382\* 45383\* Colonoscopy with ablation of tumor 45384\* Colonoscopy with removal of lesion by hot forceps or bipolar cautery 45385\* Colonoscopy with removal of lesion by snare technique G0105 Screening colonoscopy in patients at high risk for CRC,

if 23 months since last screening colonoscopy or barium enema (Medicare)

<sup>\*</sup>The Health Care Financing Administration (HCFA) allows additional payment for a tray for this procedure when performed in a physician's office. Charge appropriately using code "99070—surgical tray."

G0121 Screening colonoscopy in patients at least 50 years of age at average risk for CRC, if 119 months since last screening colonoscopy or barium enema (Medicare)

If colonoscopy is abnormal, the applicable CPT and ICD-9-CM codes (not G-codes) should be used. Conscious sedation is considered part of the colonoscopy and is not billed separately unless performed by a different provider.

## **ICD-9-CM DIAGNOSTIC CODES**

- 153.0 Ca, colon-hepatic flexure
- 153.1 Ca, colon-transverse
- 153.2 Ca, colon-descending
- 153.3 Ca, colon-sigmoid
- 153.4 Ca, colon-cecum
- 153.6 Ca, colon-ascending
- 154.1 Ca, rectum
- 211.3 Benign neoplasm, colon, or familial adenomatous polyposis (FAP)
- 211.4 Benign neoplasm, rectum-anus
- 455.0 Internal hemorrhoids
- 455.3 External hemorrhoids
- 555.1 Crohn's disease, colon
- 556.9 Ulcerative colitis
- 558.9 Colitis, nonspecific
- 562.1 Diverticulosis
- 562.12 Diverticulosis with hemorrhage
- 564.0 Unspecified constipation
- 564.5 Chronic diarrhea
- 569.84 Angiodysplasia
- 578.9 GI hemorrhage
- 787.6 Stool incontinence
- 789.0 Abdominal pain
- 793.4 Radiographic abnormality, GI tract
- V76.51 Screening, cancer, colon (to be used with G-codes; see previous discussion)

# PATIENT EDUCATION GUIDES AND ADDITIONAL RESOURCES

See patient education and patient consent forms available online at www.expertconsult.com.

Sample consent forms and patient education handouts are also available online at <a href="http://drpearlman.btrtest.com/patient\_education.htm">http://drpearlman.btrtest.com/patient\_education.htm</a> and <a href="http://springfieldasc.com/patient-information/patient-forms">http://springfieldasc.com/patient-information/patient-forms</a>.

## **SUPPLIERS**

(See contact information online at www.expertconsult.com.)

Extensive marketing and technical information about colonoscopy equipment is readily available. When selecting a supplier, the clinician should consider local availability for education, equipment service, and technical support. It may be desirable to ask for local references from suppliers.

# **ESOPHAGOGASTRODUODENOSCOPY**

Edward G. Zurad

During the past four decades, performing flexible fiberoptic esophagogastroduodenoscopy (EGD), or gastroscopy, has revealed a myriad of diseases and conditions of the upper gastrointestinal tract to primary care physicians, surgeons, and gastroenterologists. Refinements in equipment and technology have dramatically improved endoscopic diagnosis. Advancements have also permitted any interested physician, in a variety of settings, to evaluate and treat patients with both simple and complex problems of the esophagus, stomach, and the duodenum. Rapid diagnosis of upper gastrointestinal (GI) pathology with appropriate pharmaceutical and surgical management assures a high level of cost-effective care that any primary care physician can provide.

EGD is relatively quick and can be completed within 5 to 20 minutes. The procedure can be performed in various clinical environments, including the office, outpatient endoscopic suite, the hospital, or surgical center. The procedure can even be completed in the intensive care unit (ICU) or emergency room (ER) setting with a portable endoscopy cart. One study (Rodney and colleagues, 1990) indicated that when primary physicians performed EGD, it was associated with enhanced management and improved diagnostic accuracy in 89% of cases. Primary care physicians now perform flexible sigmoidoscopy, EGD, and colonoscopy on an increasingly frequent basis in their offices.

In EGD, a small flexible endoscope is introduced through the mouth (or with newer thinner diameter scopes, through the nose) and advanced through the pharynx, esophagus, stomach, and usually into the second portion of the duodenum. Both the fiberoptic and video gastroscopes are similar in construction to the flexible sigmoidoscope, the device with which many primary care physicians began to develop skills over the past three decades. Most modern endoscopes use a video chip (charge coupled device) for improved and more definitive imaging, as opposed to the older endoscopes, in which fiberoptics are used for image transmission. The tip of the scope can be moved in multiple directions. The endoscope has channels for air insufflation, air aspiration, biopsy, and water instillation.

The procedure is usually performed while the patient is under conscious sedation, although it can be completed with only topical anesthesia (a common practice in Asia). General anesthesia is reserved for a select group of patients who are difficult to sedate because of chronic narcotic drug usage or who may have allergies to the very effective agents now available for conscious sedation.

The EGD technique is also utilized when performing endoscopic ultrasound (EUS) and endoscopic interventions that are outside the realm of this chapter, including endoscopic retrograde cholangio-pancreatography (ERCP) and transthoracic echocardiography.

## **INDICATIONS**

## **Symptoms**

In many instances, it is one of the following symptoms that prompt the physician's decision to consider an EGD:

- Dyspepsia (abdominal pain)
- Dysphagia (difficulty swallowing)
- Odynophagia (painful swallowing)
- Early satiety
- Recurrent regurgitation or gastroesophageal reflux disease (GERD)
- Epigastric pain
- When swallowing, sensation of food sticking or a foreign body
- Meal-related heartburn
- Severe indigestion
- Chronic nausea and vomiting
- Substernal or paraxiphoid pain
- Severe weight loss
- Persistent anorexia
- Noncardiac chest pain

Because over-the counter (OTC) proton pump inhibitors (PPIs) and histamine-2 (H<sub>2</sub>) antagonist therapy are available, many patients independently initiate therapy for their upper gastrointestinal symptoms. They present to their primary care physician only after failing a self-directed trial of PPIs or H<sub>2</sub> antagonists. In addition, many patients have tried antacids or other agents for their upper gastrointestinal symptoms that have failed, which results in their concern for detection of the etiology of recalcitrant symptoms. EGD provides a precise evaluation to obtain a direct endoscopic assessment of the esophagus, stomach, and duodenum. Furthermore, EGD permits the physician to retrieve tissue specimens for pathologic analysis during this brief invasive procedure, which is of increasing importance.

## Signs

- Unexplained anemia
- Gross or occult gastrointestinal bleeding
- Radiographic abnormality of the upper GI tract
- Weight loss
- Abdominal mass
- Hematemesis

## **Preexisting Conditions**

Conditions that require further evaluation or surveillance with direct EGD include the following:

- Cancer surveillance in high-risk patients (e.g., those with Barrett's esophagitis, gastric polyposis, pernicious anemia)
- Esophageal stricture
- Acute or chronic duodenitis
- Acute or chronic esophagitis
- Acute or chronic gastritis
- Symptomatic hiatal hernia
- Gastric ulcer monitoring
- Gastric retention
- Duodenal ulcer disease

- Pyloroduodenal stenosis
- Esophageal or gastric varices
- Angiodysplasia in other area of the GI tract

## **CONTRAINDICATIONS**

There are relatively few contraindications to the performance of EGD. The diameter of the currently available fiberoptic endoscopes is similar to the diameter of the nasogastric (NG) tubes that are inserted on a daily basis in most hospitals. The safety of the procedure is readily acknowledged. Most primary care physicians inserted NG tubes during their early medical school education and residency training. Recalling the simplicity of these early experiences should help clinicians feel more confident about the insertion of an EGD scope.

## Contraindications to EGD include the following.

## **Absolute**

- History of a bleeding disorder (e.g., platelet dysfunction, hemophilia)
- History of profusely bleeding esophageal varices
- · Cardiopulmonary instability from any cause
- Recent myocardial infarction
- Suspected perforated viscus
- Uncooperative patient
- Absence of informed consent

## Relative

## **Anticoagulants**

Diagnostic EGD is considered a low-risk procedure for bleeding in patients taking anticoagulants and, therefore, can be performed without adjustment of anticoagulants prior to the procedure by physicians *extremely* familiar with EGD technique. Difficult or traumatic intubation of the scope could result in cricopharyngeal hematoma, which could theoretically cause carotid artery occlusion. A risk of retropharyngeal hematoma also may be present in patients with severe coagulation abnormalities.

If biopsy or polypectomy is contemplated, then the patient's coagulation profile should be normalized. Certain therapeutic procedures (i.e., dilations, percutaneous gastrostomy, polypectomy, endoscopic sphincterotomy, EUS-guided fine-needle aspiration, laser ablation, coagulation) are considered high-risk procedures for bleeding, and adjustment of anticoagulation is required. The use of low-molecular-weight heparin bridge therapy may be necessary for individuals with chronic atrial fibrillation or valvular heart prostheses in order to prevent the risk of embolic events.

## **EQUIPMENT**

Endoscopes are produced by several different manufacturers (e.g., Olympus, Pentax, Fujinon, Visions Sciences).

The typical esophagogastroscope consists of an "umbilical cord" (containing transmitted light and imaging capabilities), control head (with hand-operated wheels for up/down and left/right, air/water control buttons, and a suction button), and the long insertion tube, which is approximately 100 cm long and 7.8 to 11 mm wide. The bending section at the tip of the scope allows up to 180 degrees of deflection for retroflexion of the tip of the endoscope.

The endoscope contains a *lumen* for insufflation of *air* and *water*, a *working channel* of 2 to 3 mm diameter (larger channel diameter for therapeutic endoscopes) used for suctioning and passage of instruments, *control wires* for moving the tip of the endoscope, and the *imaging system* that is either fiberoptic (rare) or video (widely available). The endoscope light source and imaging source (either video monitor or direct-view through the eyepiece) are critical aspects of the scope. Images and video can be recorded and printed depending on the equipment used.

Flexible ultrathin fiberoptic and video endoscopes can be used without sedation for office-based EGD. Commonly used without conscious sedation, these endoscopes are inserted transnasally or perorally and have a working length of 925 to 1100 mm, an external diameter of 5.3 to 6 mm, and a working channel diameter of 2 mm. With interventional scopes, multiple instruments have been developed that can be introduced through the working channel of the endoscope. These instruments include biopsy forceps, snares, sclerotherapy needles, heater probes, electrocautery probes, balloon-dilation devices, nets, and baskets. Guidewires can be placed, and, when the endoscope is withdrawn, wire-guided bougie dilators can be utilized. Devices can also be placed onto the end of the endoscope for banding of esophageal varices and endoscopic mucosal resection.

Some of the newer endoscopes provide high resolution and magnification. Such scopes are used for the evaluation of certain upper gastrointestinal diseases. The upper endoscope is also used to guide endoscopic treatment of GERD, such as with the Bard EndoCinch endoscopic suturing device and the NDO full-thickness plicator. One of the more recent advances in video endoscopy is narrow band imaging (NBI). NBI uses optical filters and high relative intensity of blue light for imaging and assessment of mucosal morphology and topography, such as mucosal and superficial vascular patterns. NBI has been studied in patients with Barrett's esophagus, early gastric tumors, and colorectal lesions and has had promising results. Its full clinical utility has yet to be realized. In addition to the endoscope, other important equipment should be in operational order prior to starting an EGD:

- Light source (halogen light source versus xenon)
- Camera source
- Color video printer
- Video monitor
- Video recorder
- Biopsy forceps/brush
- Endoscopy table/cart
- Intravenous (IV) stand and IV sets
- Mouth guard
- Stool with wheels for the endoscopist (if he or she sits during the performance of the procedure)
- Sphygmomanometer versus continuous blood pressure monitor
- Stethoscope
- Electrocardiogram (ECG) machine or continuous cardiac monitor
- Oxygen saturation monitor (pulse oximeter) (consider Welch Allyn system that performs all necessary monitoring functions)
- Dextrose 5% and 0.45% sodium chloride solution (1 L) or lactated Ringer's solution
- Suction equipment and tubing
- Specimen jars with formalin solution
- Syringes and needles
- K-Y Jelly (water-soluble) scope lubricant
- Protective gloves (remember latex sensitivity in sensitive patients)
- Rapid urease test (CLO test) materials
- Anesthetic, sedative, and narcotic medications (see Chapter 2, Procedural Sedation and Analgesia)
- Oxygen and delivery mask or nasal cannula
- "Crash cart" supplies (consider the Banyan kit—"a crash cart in suitcase"—if procedure is being performed in the office)
- Toothpicks to remove tissue from biopsy forceps
- Dictation capabilities or computer for immediate completion of the procedural record
- Sink/supplies for cleaning the scope

## **Cleaning Supplies**

- Plastic containers for the endoscope tube
- Surgical scrub solution and water (follow the manufacturer's recommendations)
- Enzyme solution

- 70% isopropyl alcohol
- Glutaraldehyde soaking solution (follow the manufacturer's recommendations)
- Brushes and various channel insertion devices provided by manufacturer for internal channel cleaning

## PREPROCEDURE PATIENT PREPARATION

As with any procedure, EGD needs to be explained to the patient in detail prior to the procedure. The possible risks, benefits, and complications must be reviewed. It is wise to include a *patient education handout* and instructions for the patient to follow before the procedure (see the patient education handout online at www.expertconsult.com). The patient should also be given a copy of these to take home to share with a spouse or other family members.

Informed consent must be obtained before performance of EGD (see the patient consent form online at www.expertconsult.com). A preprocedure video or DVD that the patient and spouse or family member can view will reduce anxiety regarding the upcoming EGD. This video, which can be obtained from various pharmaceutical companies free of charge, will also introduce the subject of conscious sedation and review contraindications to the procedure. Figures 101-1 to 101-6 show other helpful forms for office use.

## **ANTIBIOTIC PROPHYLAXIS**

According to the latest American Heart Association guidelines, antibiotic prophylaxis for endoscopy with or without gastrointestinal biopsy is not recommended (see Chapter 221, Antibiotic Prophylaxis). No published data demonstrate a conclusive link between procedures of the GI tract and the development of bacterial endo-

carditis. No studies exist that demonstrate that the administration of antimicrobial prophylaxis prevents endocarditis in association with procedures performed on the upper GI tract.

## **SEDATION**

See Chapter 2, Procedural Sedation and Analgesia, and Chapter 7, Pediatric Sedation and Analgesia.

EGD has traditionally been performed in a hospital procedure room specializing in gastrointestinal disorders (a "GI suite"). It has also commonly been performed in an emergency room setting, an outpatient surgery facility, or a hospital operating room specially equipped for endoscopic procedures. Facility fee costs and sedation fees exceed physician reimbursement severalfold. Many physicians have completed the procedure in their offices simply using a topical anesthetic spray (Table 101-1).

Most physicians who perform EGD in their offices use a combination of a benzodiazepine and a narcotic to achieve appropriate sedation and pain control for EGD. An angiocath is usually placed when IV medications are to be used during the performance of EGD. The angiocath is connected to an IV line with IV fluids that are usually composed of  $D_5$  (5% dextrose and one half normal saline) and normal saline. It is essential that resuscitation equipment and reversal drugs are readily available throughout the course of the procedure.

Many endoscopists now routinely use oxygen delivered through nasal cannula at 2 L/min to prevent any likelihood of hypoxemia that can occur during EGD, resulting from the mechanical nature of the tube in the upper airway region. This allows for a continuous source of oxygen delivery. The patient can be stimulated to inhale by simply advising him or her to take a deep breath. If oxygen is not used in a continuous fashion during the performance of the

## **Staff Gastroscopy Instructions Guidelines**

- 1. Be sure the patient has a copy of the patient teaching guides and that he or she understands and has read the instructions.
- Advise the patient that the purpose of the study is to insert a tube through the mouth into the stomach and into the beginning
  of the small intestine in order to inspect the upper GI tract. We will be looking for inflammation, ulcers, growths, bleeding points,
  a hiatal hernia, and abnormal growths.
- 3. The following medications will probably be used: a "Caine" topical anesthetic, Demerol, and Valium or Versed. Be sure to inquire about sensitivity or allergy to any of the medications just mentioned. These medications act to depress the central nervous system. The patient's current medications, particularly tranquilizers, sedatives, sleeping pills, and muscle relaxants, must be reviewed, and their effects when taken with preprocedure medication must be considered.
- 4. Possible serious side effects are extremely unlikely, but they include bleeding, perforation of the GI tract, tearing of the vocal cords (voice box), aspiration of stomach contents into the lungs, tearing of the mucosa, or even death from a severe reaction (e.g., to medications).
- 5. All patients will have gagging, but very few (if any) will experience any discomfort with gagging if they take the full prep. Patients who take the full prep will be groggy, sleepy, or lethargic for a variable period after the procedure. They must not drive or do anything "delicate" for at least 4 hours following the procedure if they received a prep. If grogginess persists, they should wait until they are fully alert. We recommend waiting 8 hours, if possible. If patients have a medical condition that affects medication metabolism, the wait will most likely be longer.
- 6. The procedure can be performed in a highly motivated patient without any preparation, but the gagging is uncomfortable and tends to persist throughout the procedure. It does, however, decrease after the scope is partially inserted. A topical anesthetic spray will greatly decrease gagging in the patient who chooses to not have IV sedation.

Be sure to be aware of the following:

Recent use of:

ASA

Persantine

Motrin

Advil

NSAIDs

Coumadin

Plavix

Preexisting disease:

Asthma

Heart disease

COPD

Phlebitis

Prosthetic valves or joints

If plans to deal with any of the above medications or preexisting diseases are not recorded in the chart, please discuss with the physician how to handle the situation.

## Guidelines for Monitoring the Patient Receiving Sedation and Anelgesia for Gastrointestinal Endoscopy: A Summation

- 1. Patient monitoring is one aspect of the overall quality assurance program for the endoscopy unit.
- 2. A well-trained gastrointestinal assistant, working closely with the endoscopist, is the most important part of the monitoring process.
- 3. The use of equipment to monitor patients may be a useful adjunct to patient surveillance, but it is never a substitute for conscientious clinical assessment.
- 4. Although changes in blood pressure, pulse, cardiac rhythm, and oxygen saturation do occur during endoscopy, no controlled studies address the question of whether noninvasive monitoring with equipment decreases complications.
- 5. The amount of monitoring should be proportional to the perceived risk of the patient undergoing the procedure. It may vary from one procedure to the next.
- The minimal clinical monitoring advised for all sedated patients should include the determination of heart rate, blood pressure, and respiratory rate before sedation, during the procedure, immediately after the procedure, and when the patient is released from the endoscopy area.
- 7. The proper role for pulse oximetry and continuous electrocardiographic monitoring during endoscopic procedures is controversial and unsettled.
- 8. Given the cost of the equipment and the manpower to use it, the best decision as to whether such monitoring should be used would be based on data showing an effect on clinical outcome. Such data do not exist; however, in those situations in which the individualized need of the patient indicates that measurement of cardiac rhythm or oxygen saturation will complement the clinical assessment, the use of cardiac monitoring or pulse oximetry may be beneficial.

EGD Procedure					
Name:			BD:_	Da	te:
The patient gave informed consent for the procedure. Intravenous access was obtained in the R/L upper extremity. Topical anesthesia was used in the pharynx. The patient was placed in the left lateral position, and the neck flexed to the chest. The bite block was placed gently, and the scope lubricated and passed through the bite block over the tongue. The hypopharynx was visualized, the vocal cords visualized, and the scope passed through the cricopharyngeus. The scope was passed into the distal esophagus with the GE junction seen and diaphragmatic indentation noted by the sniff test. The scope was advanced into the stomach and the gastric lake suctioned. The scope was passed through the pylorus and maneuvered into the descending duodenum. The duodenum and duodenal bulb were visualized and the scope brought back into the stomach. A biopsy for CLO testing was obtained. The scope was retroflexed to view the cardia. The scope was pulled into the esophagus and the esophagus closely examined. The scope was withdrawn, and the patient tolerated the procedure well. Monitoring showed normal cardiac/oxygen status. The patient was informed of the procedure results. Pulse oximetry monitoring was used throughout the procedure to evaluate the patient for hypoxemia. A printed report is attached. Changes to above procedure: None or

procedure, oxygen must be available in the event that hypoxemia occurs.

Midazolam (Versed) is a sedative/hypnotic commonly used for sedation. The peak effect of midazolam is seen within 3 to 5 minutes. It has a duration of action of 1 to 3 hours. Some of the major adverse effects include respiratory depression, hypotension, and rarely seen paradoxic agitation. The typical starting dose is 0.5 to 1 mg IV, which can be titrated to achieve a desirable level of sedation (usually in 1-mg increments every 2–3 minutes). Lower doses of midazolam should be administered to elderly patients with cardiopulmonary problems to avoid serious respiratory depression.

Diazepam (Valium) may be used instead of midazolam for sedation during EGD, but many centers prefer midazolam (over diazepam) because of its well-received amnestic effect and reduced tendency to cause local vein phlebitis. Diazepam is initiated at 1 to 2 mg IV and titrated at 2-mg doses given every 1 to 2 minutes. This agent can also cause respiratory depression and should be used carefully in elderly patients. Paradoxic excitation can be seen with this sedative.

Benzodiazepines can rarely cause paradoxic excitement. If it occurs, however, pure narcotics can usually be used to complete the procedure. In extreme cases cancel the procedure and reschedule it when assistance with sedation is available.

Meperidine (Demerol) is a narcotic analgesic that has mild sedative properties, slow onset of action, long duration, and long recovery time. When coadministered with benzodiazepines, potential complications include respiratory depression and sedation. The peak effect of meperidine is approximately 10 minutes, with a duration of action of 2 to 3 hours. Adverse effects include respiratory depression, hypotension, nausea, and vomiting. The typical starting dose is 12.5 to 50 mg IV, with subsequent doses not to exceed 25 mg/dose.

Fentanyl (Sublimaze) is a mildly sedative narcotic analgesic that has a rapid onset of action and short recovery time. In many endoscopy centers, fentanyl is the preferred agent for outpatient EGD. The peak effect is 5 to 8 minutes, and the duration of action is 1 to 3 hours. One of the major adverse effects is respiratory depression. The typical starting dose is 0.03 to 0.1 mg IV, with subsequent doses of 0.02 to 0.05 mg/dose.

When IV sedation is used, the end point to be titrated is slurred speech with the patient still able to be aroused.

Several agents are used as *reversal agents* for conscious sedation. Physicians employing conscious sedation should be very familiar with these agents. Naloxone (Narcan) reverses opioid-induced analgesia, central nervous system (CNS) effects, and respiratory depression. Naloxone has a peak effect of 1 to 2 minutes and a potential duration of action of 1 to 3 hours. Adverse effects include pain, agitation, nausea, vomiting, arrhythmias, sudden death, pulmonary edema, and withdrawal syndrome in patients with chronic opioid abuse. The typical dose is 0.04 mg IV for reversal of

## Role of the Assistant

The well-trained and motivated assistant makes the EGD examination a pleasant task for the physician. It is not necessary for the attendant to attend a special course, but it is necessary to spend time learning each step of the procedure. Representatives from the endoscope manufacturer will assist in training assistants in the cleaning and care of the scopes. It is important to have assistants trained in CPR.

Before the patient arrives for the procedure, the assistant must do the following:

- 1. Prepare the room.
- 2. Have the IV set up, medications, endoscope, and the resuscitation equipment ready (but not opened).
- 3. Prepare the paperwork.

When the patient arrives, the assistant must do the following:

- 1. Bring the patient to the procedure room.
- 2. Orient the patient to the room and the equipment.
- 3. Make sure consent forms are signed, and that the patient has read and understands the instructions.
- 4. Verify that the patient is properly prepared (NPO, has a qualified adult to accompany the patient home). Check patient allergies.

Review and record current patient medications.

- 5. Review the EGD procedure with the patient.
- 6. Record baseline vital signs.
- 7. Place EKG monitor pads and initiate oximetry and cardiac monitoring if indicated.
- 8. Initiate IV fluids at KVO if IV sedation used.
- 9. Give the patient topical anesthesia within 3 to 5 minutes of starting the procedure.

During the procedure, the assistant must do the following:

- 1. Record vital signs every 15 minutes during the procedure.
- 2. Assist the endoscopist with the scope, if needed.
- 3. Watch the monitoring equipment, and notify the physician of changes in patient status.
- 4. Assist with obtaining multiple biopsies and brushings.
- 5. Receive and process biopsy specimens and paperwork.

After the procedure, the assistant must do the following:

- 1. Monitor the patient's vital signs for 15 minutes.
- 2. Secure the safety of the patient, raise the gurney rails, etc.
- 3. Complete the paperwork associated with the procedure.
- 4. Remove monitoring equipment from the patient.
- 5. Clean the equipment.
- 6. Discontinue the IV fluids, if used.
- 7. Clean the room for the next procedure.
- 8. Prepare the patient for the physician conference.
- 9. Give the patient the instruction sheets.
- 10. Inform the person accompanying the patient of signs to observe.

Figure 101-6 Sample form detailing the role of the assistant. (From The Medical Procedures Center, Midland, Mich.)

analgesia/sedation and 0.4 mg for narcotic overdose and respiratory arrest.

Flumazenil (Romazicon) is typically used for reversal of benzodiazepine-induced sedation and respiratory depression. Flumazenil has a peak effect of 3 to 5 minutes and a duration of action of 1 to 2 hours. Potential adverse effects include resedation and seizures. The typical dose is 0.2 to 0.5 mg IV for reversal of sedation (up to 1 mg total) and 1 to 3 mg IV for benzodiazepine overdose. This agent must be used with care in patients who are chronic anxiolytic users because it could cause the onset of seizures.

The use of monitored anesthesia care (MAC) and propofol (Diprivan) has developed widespread patient acceptance because of the short recovery time required for the patient. Such an approach is typically utilized in outpatient surgical centers, hospitals, or GI endoscopic suites. Many institutions have special guidelines regarding the use of propofol due to its possible potent adverse effects, which include apnea and hypopnea.

Sufficient anesthesia or sedation can often be accomplished without IV drug administration, using new approaches that are called *non-IV conscious sedation*. With this technique, a patient can be given diazepam 10 mg orally 1 hour before the procedure, or lorazepam 1 to 2 mg sublingually 30 to 60 minutes before the procedure. Halcion, 0.5 mg orally, can also be used. An optional intramuscular dose of ketorolac (Toradol) 60 mg may be given 30 to 60 minutes before the procedure.

Butorphanol tartrate (Stadol), 1 to 2 sprays (intranasally), can be added if needed to the preceding regimen, or used alone. It generally provides both sedation and analgesia sufficient to carry out EGD. In many countries, EGD is performed with topical anesthesia only. Topical anesthesia with a benzocaine and tetracaine mixture (Cetacaine) or lidocaine has the advantages of requiring less time for the overall procedure, eliminating the risks of conscious sedation, and decreasing the cost of the procedure by reducing or eliminating recovery time and nursing staff and anesthesia personnel. The spray is directed toward the posterior osopharynx while advising the patient to avoid breathing during the application. Inhaling the spray can cause significant coughing and gagging.

The disadvantages of using only topical anesthesia are patient discomfort and problems in performing the procedure on an uncooperative patient. An *alternative choice* for *topical anesthesia* is the "popsicle stick" method. In this scenario, lidocaine ointment (2%) is squeezed on a tongue blade that is covered with the patient's favorite food flavoring, and this is placed into the back of the patient's throat. The patient sucks on the tongue blade while vital signs are completed and the patient is prepared for the procedure. A tongue blade can be pressed into the posterior oral pharynx to ascertain that appropriate topical anesthesia has been obtained before insertion of the endoscope. Lack of a gag reflex ensures the desired effect. With the cost-saving trends in medicine, and with the newer, smaller scopes, EGD without sedation will likely become more

TABLE 101-1 Drugs Used for Esophagogastroduodenoscopy			
Medication	Dose		
Narcotics Meperidine (Demerol) IV Fentanyl (Sublimaze) IV Butorphanol tartrate (Stadol Nasal Spray) Propofol	I 0–75 mg (0.5–I mg/kg) I–2 mg I–2 mg (I–2 sprays in nostril)  Variable*		
Benzodiazepines Diazepam (Valium) IV Midazolam (Versed) IV Lorazepam (Ativan) SL (onset in 10 min) Triazolam (Halcion) PO	I-10 mg 2-5 mg (0.035-0.1 mg/kg) I-2 mg 0.5 mg		
Anticholinergic Glycopyrrolate (Robinul)	0.002 mg (0.01 mL/kg) IM I hour before procedure or 0.1 mg (0.5 mL) repeated every 2–3 minutes as needed		
Miscellaneous Simethicone (Mylicon) drops Ketorolac (Toradol)	0.6 mL (30–40 mg) in 30 mL of water PO (can also be flushed through the gastroscope with 5 mL of water) 60 mg IM; 15 mg IV		
Topical Local Anesthetics Lidocaine 2% viscous solution gargle Benzocaine 20% (Hurricaine) spray Benzocaine 14% and tetracaine 2% (Cetacaine)			
Antagonists Naloxone (Narcan) IV Flumazenil (Romazicon) IV  Nalmefene hydrogen chloride (Revex)	0.2–0.8 mg 0.2–1 mg (start with 0.2 mg; repeat every 60 sec. to a maximum of 1 mg or until reversal of benzodiazepine effect has been achieved) 1–2 mL IV		

IM, intramuscular; IV, intravenous; PO, orally; SL, sublingually.

\*Sedation may be initiated by infusing propofol at 100 to 150 mcg/kg/min (6 to 9 mg/kg/h) for a period of 3 to 5 minutes and titrating to the desired clinical effect while closely monitoring respiratory function.

commonplace in the future. With the introduction of the previously described smaller caliber endoscopes that can be passed through the nose, EGD without sedation may be more acceptable to patients.

Currently available small-diameter scopes allow for a comfortable examination with little manipulation or trauma to the cricopharyngeal region. As stated previously, the diameter of the scope is similar to that of an NG tube inserted daily by hospital nursing staffs.

It is important to select patients wisely for office-based EGD. This is a critical step. In individuals who are in the high-risk group (Box 101-1), the clinician should consider performing EGD in a facility where complications can be handled and more aggressive monitoring procedures can be carried out. The utilization of MAC is suggested in such cases.

## **MONITORING**

The current move to office endoscopy was initiated because of its many benefits, including safety and cost effectiveness. The American Academy of Family Physicians and the Joint Commission for Accreditation of Hospitals and Organizations do not recommend continuous ECG monitoring or continuous pulse oximetry for low-

# Box 101-1. High-Risk Groups for Esophagogastroduodenoscopy

Agitated, uncooperative patient
Barium administration within a few hours of the procedure
Cardiopulmonary instability of any type
Current active bleeding
Older than 70 years old
Prosthetic cardiac valves
Recent cerebrovascular accident
Significant bleeding disorder or coagulopathy
Significant chronic obstructive pulmonary disease
Significant valvular heart disease
Uncontrolled coronary artery disease

risk patients. More extensive monitoring becomes necessary under the following conditions:

- Procedures that last longer than 30 minutes
- Large-bore scopes
- Individuals with significant cardiopulmonary disease
- Elderly patients (over 70)

Younger than 12 years old

- High-risk patients (see Box 101-1)
- Situations in which more than "light" sedation is used

In these scenarios more extensive clinical monitoring, including continuous ECG monitoring and pulse oximetry, is wise. All patients should have clinical monitoring of skin color, degree of sedation, loss of reflexes, blood pressure, pulse, and respiratory rate in a well-lighted room.

## **TECHNIQUE**

It is essential to ensure that aspirin, clopidogrel (Plavix), and platelet-inhibiting nonsteroidal anti-inflammatory drugs (NSAIDs) have been discontinued at least 7 days before the procedure. The patient must take nothing by mouth after midnight on the day of the examination (or at least 8 hours must have elapsed since eating).

The assistant should initiate the IV angiocath and connect it to the IV line. If pulse oximetry and continuous ECG monitoring are to be utilized, connect them at this time. Blood pressure, pulse, and respiration monitoring can also be started at this time and recorded.

- 1. Examine the oral cavity while the patient is in a sitting position. Any dentures or foreign objects should be removed.
- 2. If using a fiberoptic scope, ask the patient to swallow 40 mg of *simethicone* in 30 mL of tap water before the initiation of the procedure. This tends to minimize the reflective bubbles in the stomach (Fig. 101-7) that present considerable impediment to visibility during the procedure. Alternatively, simethicone can be used only if needed during the procedure (0.6 mL of simethicone liquid can be injected down the gastroscope followed by 5 mL of water).

Figure 101-7 Bubbles in the stomach.

- The topical anesthesia should be completed at this point, as noted previously.
- 4. After good *topical anesthesia* is ensured, the patient should be placed in the left lateral decubitus position, especially if sedated. Unsedated ECDs are often performed in the sitting position with the patient bent 45 degrees forward at the waist.
- Lubricate the distal 10 cm of the scope with a minimal amount of water-soluble gel (an excessive amount may induce coughing or sneezing).
- 6. *Insert the mouth guard* into the patient's mouth; the teeth should grip this guard. The guard not only protects the patient's teeth, tongue, and oral mucosa but it also prevents the patient from damaging the scope. Introduce the scope through the mouth guard and direct it across the superior aspect of the tongue into the posterior oral pharynx.

In the edentulous patient, the mouth guard can be placed over the scope and the scope can then be introduced through a channel created by placing the left second and third fingers of the examiner's hand over the back of the tongue.

Guide the scope across the back of the tongue into the cricopharyngeal region. This is usually the first point of resistance encountered (approximately 17 cm from the incisor teeth and at the level of the vocal cords) (Fig. 101-8).

Under direct vision, or blindly, ask the patient to swallow repeatedly while applying gentle pressure. The scope will easily pass through the *cricopharyngeus region* without difficulty and can then be advanced down through the esophagus (Fig. 101-9A and B).

- 7. *Never* use force as the scope passes the cricopharyngeus region. The patient's normal swallowing mechanism will assist in advancing the endoscope.
- 8. Once the tip of the endoscope has entered the esophagus, insufflate a small puff of air to open the esophagus to easily visualize the mucosa throughout the cylindric esophagus. Additional air will need to be insufflated after the scope reaches the stomach and duodenum.

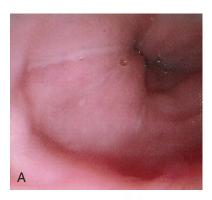

**NOTE:** Identify the channel in front of the scope before attempting to pass the scope to prevent injury to the patient. The lumen should always be seen during EGD.

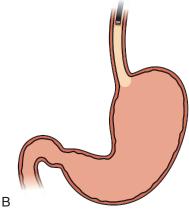

The endoscope should be advanced quickly but gently through the esophagus. The first landmark seen is the *bronchioaortic constriction* (Fig. 101-10).

- 9. As the scope is advanced, the *gastroesophageal* (GE) *junction* (Z *line*) is typically found at approximately 40 cm from the incisor teeth. It is essential to evaluate the esophagus and GE junction during this "first pass," because the mucosa may become irritated by the passage of the scope. This irritation can distort the appearance of the GE junction (Fig. 101-11A and B). There is a typical mucosal color demarcation that occurs at the GE junction, with the esophageal lining being pale pink and the gastric mucosa represented by a darker pink or orange hue.
- 10. At this time, ask the patient to sniff through his or her nose (i.e., the "sniff test") if the patient is partially conscious. As the patient sniffs, the crura of the diaphragm extrinsically compress the GE junction at the esophageal hiatus. If the Z line is visualized above the level of the extrinsic compression seen from the

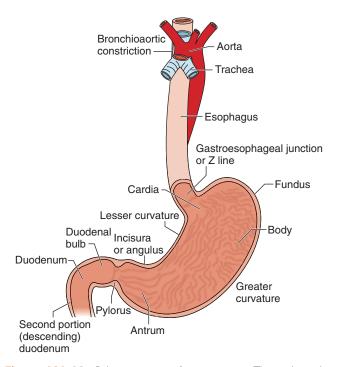

Figure 101-8 Open vocal cord.

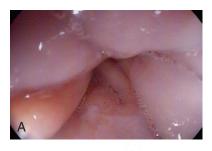

**Figure 101-9 A,** Proximal esophagus. **B,** Unshaded area is seen by lighted scope.

**Figure 101-10** Relevant anatomy for gastroscopy. The *cardia* is that portion of the stomach immediately surrounding the esophageal opening. The *gastroesophageal junction* is also known as the GE junction, the Z line, ora serrata, or gastric rosette. The upper end or dome of the stomach is the *fundus*. The upturn of the J of the stomach is separated from its vertical portion by the *angular* notch (also known as the angulus, angularis, or incisura). The *antrum* lies to the right of the angulus and ends at the *pylorus*, or greatly thickened muscular wall. The *duodenum* lies beyond the pylorus. The *lesser curvature* is the upper right border of the stomach, whereas the *greater curvature* is the left inferior margin.

**Figure 101-11 A,** Distal esophagus Z line. **B,** Unshaded area is seen by lighted scope.

crura of the diaphragm, then the patient is suffering from a *hiatal* hernia. Repeat the sniff test when viewing the Z line from below, while the scope is in the stomach in a retroflexed position.

**NOTE:** Use air, water, suction, and "miniwithdrawals" as needed to pass the scope and to fully evaluate all surfaces of the mucosa.

11. After passing through the GE junction, the endoscope is inserted into the *stomach*. After the scope reaches the stomach, the gastric lake, which is a collection of fluids in the dependent portion of the stomach, will typically impair visibility (Fig. 101-12A and B). Air should be insufflated sufficiently to spread the mucosal walls apart so that this fluid can be aspirated. Some clinicians aspirate the gastric fluid and test the pH of the fluid to record the acidity of the gastric lake. After the fluid is removed and the lumen again is clearly visualized, the scope can rapidly be advanced following the rugae along the lesser curvature to the *angular notch*. The scope is subsequently passed below the angularis, then into the antrum and up to the pylorus (Figs. 101-13A to E, and see Fig. 101-10).

**NOTE:** The scope should be adjusted so that the small black arrow is at the top of the field and so it corresponds with the incisura. This adjustment provides proper orientation with the patient in the left lateral position.

12. Guide the endoscope through the relaxed pyloric sphincter into the duodenal bulb (Fig. 101-14A and B). Do not attempt to pass the scope through a tightly closed pylorus. The repetitive trauma of attempting to do this will simply cause greater pylorospasm and prevent good evaluation of the duodenum. When the scope is passed through the pylorus into the duodenal bulb, it is common to encounter a *white-out* or a *red-out*. This is because the scope typically tends to rapidly advance to the junction of the first and second portions of the duodenum and press against the mucosal. At this point it is wise to withdraw the scope very slowly to reestablish the lumen and complete the duodenal examination. Biopsies are rarely needed in this area.

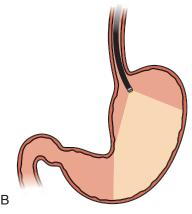

Figure 101-12 A, Gastric lake with reflective bubbles/fluid seen from I to 3 o'clock. B, Unshaded area is seen by lighted scope.

- 13. The second portion of the duodenum becomes retroperitoneal. Thus, it is wise to turn the scope to the right and pass the scope downward so that it can enter the second portion of the duodenum (see Fig. 101-13). The second portion of the duodenum is recognizable because of the vertical, cylindric nature of the viscera in this region. In addition, the Kerckring's folds (Fig. 101-15A) will readily appear. The ampulla of Vater (Fig. 101-15B) can be seen along the medial aspect of the second portion of the duodenum 20% to 30% of the time. It is not essential to evaluate this area for the completion of an EGD.
- 14. The scope can be advanced occasionally into the *third portion* of the duodenum or the horizontal portion of the duodenum.

**NOTE:** At this point of the procedure, the insertion portion is complete, and it is time to withdraw the scope.

- 15. Withdraw the endoscope slowly with the attempt to evaluate the entire 360-degree circumferential portion of the mucosal surface. The second and sometimes the third portions of the duodenum can be evaluated readily.
- 16. The *duodenal bulb* is difficult to assess because, as it is being withdrawn, the scope typically tends to rapidly retract through the pyloric junction, back into the stomach. It is therefore necessary to reinsert it through the pylorus so that the duodenal bulb mucosa can be closely examined to rule out disease.
- 17. Once back into the stomach, it is helpful to deflect the scope tip up and down as the control head is rotated right and left to ensure that the entire gastric mucosal surface has been evaluated. If not previously performed, retroflex the scope so that it is viewing itself and observe the GE junction. Examine the cardia and fundus (Fig. 101-16A to D).
- 18. Straighten the scope tip deflections before removing the scope through the GE junction. One way to do this is to align the letters on the large inner wheel (up/down control) and the small outer wheel (left/right control) before withdrawing the instrument. If the scope is withdrawn with the tip retroflexed, it could result in mucosal damage of the GE junction or an esophageal tear.

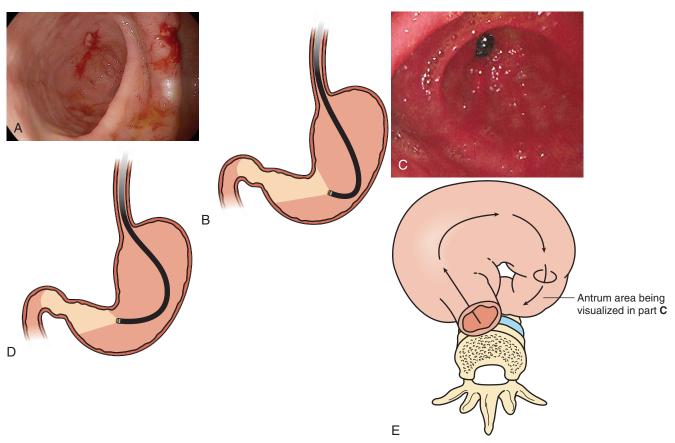

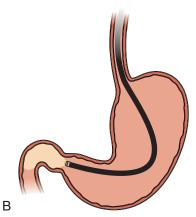

Figure 101-13 A, Angularis is along the right side of visual field. Pyloris is in the distance but cannot be seen due to angularis obstructing the view. Prepyloric ulcer is seen at 11 o'clock. B, Unshaded area is seen by lighted scope. C, Antrum at the 6 o'clock position. Pyloric opening and angularis at the 12 o'clock position. D, Unshaded area is seen by lighted scope. E, To reach the pylorus, the clinician should make a clockwise spiral around the vertebral column.

- 19. The scope is withdrawn through the GE junction slowly. Again, close evaluation of the GE junction is completed. Complete a sniff test at this region one final time.
- 20. As the procedure is being carried out, photographs can be taken on a continuing basis, both during the initial insertion and during withdrawal.
- 21. Biopsies during EGD are completed as the scope is withdrawn to prevent significant downstream bleeding that can impair visibility of the mucosal surface (see the "Biopsy" section).22. It is important to record the appearance of the vocal cords before
- 22. It is important to record the appearance of the vocal cords before the scope is withdrawn. The documentation of an attempt to view the vocal cords is an important component of EGD before

- the removal of the scope, even if they cannot be seen because of coughing or gagging.
- 23. The assistant should complete the monitoring process of the patient after the scope is withdrawn. The mouth guard should also be removed, and the physician may want to reexamine the patient before discharge from the facility. A 30-minute observation period after the procedure is typical if minimal sedation is used (Box 101-2).
- 24. Discuss the findings with the patient (and the person who has accompanied the patient to the office) before discharge. If the patient has received significant administration of benzodiazepines, such as midazolam (Versed), he or she may be amnestic

## Box 101-2. Intravenous Sedative Administration Recovery Nursing Documentation Parameters

- Note and record level of consciousness on arrival.
- Note and record response and anxiety level.
- Note and record patency of airway, spontaneous respiratory effort.
- Note and record status of intravenous (IV) access site (redness or edema).
- Note and record respiratory effort and degree of chest movement
- Note and record vital signs every 5 min.
- Place the cardiac monitor.
- Place the pulse oximeter.
- Note and record body temperature.
- Administer oxygen at 2 L through a nasal cannula.
- Raise head of the bed 30 to 45 degrees.
- Note and record skin turgor.
- Note and record quality of speech (clarity and ease of speech).

- Note and record presence or absence of nausea, gagging, spasmodic coughing, and ability to swallow.
- Note and record presence or absence of abdominal distention or tenderness.
- Note and record quality of bowel sounds.
- Note and record expulsion of gas.
- Note and record abdominal cramping.
- On admission, perform an assessment of the patient's medical conditions.
- Note and record any untoward symptoms as they occur.
- Note and record the patient's condition after 15 min.
- Note and record discharge status.
- Record vital signs every 5 min and post monitor strips, with a simple explanation, every 15 min or when there is an unusual occurrence.
- Report any unusual responses immediately to the physician.

and forget any information provided by the physician. Photographic records of the findings, along with graphic demonstration or written comments, are extremely helpful in reviewing the results of the procedure with the patient and his or her family. Complete and review all monitoring forms.

- 25. The gastrointestinal assistant should document the condition in which the patient was discharged.
- 26. It is helpful to call the patient at home at the end of the day (before the office closes) to document that the patient is not experiencing any untoward effects after the completion of EGD.

# UNSEDATED TRANSNASAL ESOPHAGOGASTRODUODENOSCOPY

With the advent of newly developed ultrathin diameter endoscopes (5.1- to 6-mm insertion tube), unsedated transnasal EGD (T-EGD) has become possible. Unsedated EGD obviously eliminates the danger of medication-related complications from sedative drugs. More than half of the morbidity and mortality attributed to EGD is due to cardiopulmonary complications from sedation effects.

Significant cost reduction is associated with the absence of fees for sedation and monitoring equipment. This alone has become a significant motivational factor to encourage office-based T-EGD.

Previously, either the patient or the physician may have opted for an empiric therapeutic trial of medications for a myriad of upper gastrointestinal complaints rather than having an EGD. Such choices may have been based on patient anxiety or physician concerns about the procedure. Such a delay in diagnosis is no longer necessary because T-EGD can be completed easily and rapidly in the office, eliminating the need for nursing time and anesthesia personnel. Also preoperative, concurrent, and postoperative monitoring with a pulse oximeter are no longer issues.

Other hidden costs can also be eliminated. Such costs include the drain on the economy's workforce associated with the current need for family members or friends taking time off to assist and transport patients for EGD. Patient convenience is enhanced, because endoscopies can be performed during office hours. No lengthy recovery period or check-in or discharge time is required. Patients can return to work almost immediately following T-EGD. Physicians can perform more endoscopies in less time after they are trained and familiar with the unsedated technique.

A remaining hurdle is the fact that most patients experiencing EGD have come to expect that they will sleep through their procedure and awaken with little or no awareness of what was done. Patient apprehension can be a major obstacle. This concern can be overcome with good patient education (such as videos of actual procedures), which will increase acceptability and tolerance. Patients can actually watch their anatomy on the screen and actively communicate (talk during the procedure), providing feedback to the physician. Immediate demonstration and explanation of the pathology are possible with a conscious patient who is viewing the procedure as it occurs. Biopsies can now be performed with newer generation transnasal endoscopes to allow for tissue retrieval.

## **BIOPSY**

Biopsy samples are taken when visible changes are seen in the stomach or esophagus. Routine, blind biopsy specimens of the esophagus, stomach, or duodenum are *not* indicated. The clinician should perform a biopsy on any gastroesophageal abnormality, unless it is vascular in appearance (i.e., pulsating or bluish in color). Any intended areas of biopsy should be approached with a closed biopsy forceps to assess the vascularity and induration of the subject area. The clinician should ensure that the intended biopsy site can be successfully reached with the scope in its current position. Biopsy of duodenal ulcers is rarely necessary because the risk of cancer is extremely small in this region.

During biopsy, the forceps are advanced through the end of the scope by the examiner, and the assistant is in charge of the operating controls. The closed forceps are directed at the area to be biopsied (Fig. 101-17A).

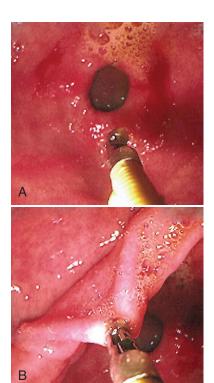

After reaching the desired site with the closed forceps, the forceps are withdrawn a few centimenters, the assistant is advised to open the forceps, and the forceps are passed directly into the biopsy area. The examiner asks the assistant to close the forceps. A gentle tug is given, and the biopsy forceps are pulled through the opening of the scope by the examiner. Tenting of the mucosa can be seen with the removal of the tissue (Fig. 101-17B).

The assistant then retrieves the tissue by opening the biopsy forceps over a container with formalin. A toothpick is placed into the teeth of the open biopsy forceps, dislodging the tissue material into the formalin container.

For gastric ulcers, the clinician should biopsy all four quadrants at the edges. Removal of tissue from the center of the ulcer will not result in adequate tissue examination. If diffuse intestinal gastritis is present, multiple biopsies are indicated. Because the biopsies are small, there is generally minimal bleeding. In most cases bleeding from esophageal biopsies stops within 4 to 5 minutes.

It is unnecessary to continuously monitor a biopsy site during the performance of the procedure. Commonly, the examiner can complete the examination by looking at other areas of the upper GI tract and then return to reevaluate a biopsy site before the completion of the procedure. If bleeding does occur and is profuse, it must be controlled before withdrawing the scope and noted on the operative report. In most cases, the acidic milieu of the stomach coagulates bleeding sites. Occasionally the distal esophagus will bleed more persistently after the completion of a biopsy; therefore, many examiners perform brush "biopsies" in this region rather than the surgical biopsy.

Gastric biopsies are also commonly done to obtain tissue samples for CLO tests or for histologic analysis for Helicobacter pylori. H. pylori—associated gastritis often cannot be diagnosed by endoscopic appearance alone. When assessing a patient with chronic dyspepsia, the

**Figure 101-17 A,** Closed biopsy forceps. **B,** Tenting of the mucosa during biopsy.

clinician should remember that normal-appearing gastric mucosa may exhibit marked histologic gastritis.

When performing the CLO test, the examiner should warm the slide to room temperature before the endoscopy. The absence of bismuth preparations and a 4-week abstinence from antibiotics should be documented before the performance of the procedure.

When performing *H. pylori* biopsies, the clinician should obtain tissue samples from the *normal-appearing* portions of the gastric antrum. The normal-appearing area of the mucosa is chosen because *H. pylori* may be scarce in areas where the epithelium is eroded or where the mucous layer is denuded.

Many physicians read and interpret the results of a CLO test (a simple color change) themselves. However, the tissue can be sent to a pathologist. Some physicians collect two specimens: one for a CLO test and one for histologic analysis (the histologic analysis specimen is sent only if the CLO test is negative but there is a strong suspicion of *H. pylori*). A single biopsy has a sensitivity of approximately 95%, whereas two biopsies approach 100% sensitivity. *H. pylori* have a patchy distribution.

## **COMPLICATIONS**

The complication rate of endoscopy performed by primary care physicians from eight clinical sites was 0.0014 (1 in 717). All cases were collected sequentially from the beginning of each physician's experience (Rodney and colleagues, 1990). The complication rate in large subspecialty populations is 0.0013 (1.3 in 1000). Therefore, complications from EGD are extremely rare. Sixty percent of the adverse effects associated with EGD are due to cardiopulmonary complications that arise directly from the conscious sedation used in the procedure. True complications might include the following:

- Perforation
- Bleeding secondary to trauma or biopsy
- Infection
- Cardiopulmonary complications from conscious sedation
- Inadequate interpretation

The risk of perforation is increased when therapeutic procedures (not discussed in the text) are performed at the time of endoscopy. Risk increases as follows:

- Esophageal dilation, 0.5%
- Esophageal dilation for achalasia, 1.7%
- Endoscopic thermal therapy, 1% to 2%
- Endoscopic variceal sclerotherapy, 1% to 6%
- Endoscopic laser therapy, 5%
- Photodynamic therapy, 4.6%
- Esophageal stent placement, 5% to 25%

## COMPLETION OF THE EGD REPORT

The final EGD report can be completed on a preconstructed template (Fig. 101-18) or a computer template macro, or it can be dictated into a transcription system. The report should include the diagnosis and the symptoms or signs that led to the performance of the EGD. Inclusion of the sedative agents and doses is important to incorporate especially if future endoscopy is contemplated. All of the findings should be detailed. A listing of the final diagnoses and treatment plan is essential to include. The physician should also note the number of biopsies and the location from which they were obtained.

## **TRAINING**

Most physicians who are performing primary care endoscopy have received training either in a residency situation or in short courses such as those through The National Procedures Institute. Both of these training situations provide excellent introduction to the technique of EGD, the use of conscious sedation, and the interpretation of common pathologic conditions seen with the endoscope.

It is essential for the clinician to obtain preceptor training from a skilled endoscopist who can assist with the proper insertion technique and the proper interpretation of anatomic findings during the performance of EGD.

There is no common agreement concerning how many procedures a clinician who is already competent at other endoscopic procedures (e.g., flexible sigmoidoscopy, colonoscopy) should perform before performing EGD without supervision. Many skilled primary care endoscopists believe that approximately 5 to 15 examinations under supervision are adequate. This number is significantly less than a specialist who will be doing more advanced therapeutic/interventional care rather than diagnostic evaluation.

## **OBTAINING HOSPITAL PRIVILEGES**

Hospital privileges remain a strongly contested area; the debate over who should receive these privileges is primarily motivated by subspecialty concerns. There are absolutely no study-supported data in the literature denoting a minimal number of procedures that should be supervised before obtaining hospital privileges. Although many numbers are reported by subspecialty organizations as a proposed minimum, these numbers are subject to debate and are not in any way a demonstration of individual competency. Thus, it is essential to have a skilled endoscopist act as preceptor to an individual to ascertain adequate eye-hand coordination and good visual-spatial skills. For more information, the clinician should review the American Academy of Family Physicians' position paper on endoscopy at www.expertconsult.com.

# MANAGEMENT OF FECAL IMPACTION

George G. Zainea

Fecal impaction is a common condition that typically occurs in the bedridden or nursing home patient. Individuals who suffered a cerebrovascular accident are at particular risk. Fecal impaction is the most common gastrointestinal disorder occurring in patients with a spinal cord injury. Medications such as narcotics predispose to this problem. It is also a common complication of anorectal procedures as a result of reflex spasm of the anal sphincter. Painful anal fissures may cause the same problem.

## **DIAGNOSIS**

Fecal impaction should be suspected when a patient has unexplained constipation or diarrhea. Diarrhea occurs as liquid stool passes around the hard fecal bolus. Rectal distention from the fecaloma causes reflex relaxation of the internal anal sphincter. The patient may have acute or chronic large bowel obstruction, both clinically and by radiographic examination. The chronic obstruction will increase mucosal water and electrolyte secretion, leading to frequent, loose, watery stools that pass around the bolus. The patient with spinal cord injury may demonstrate autonomic hyperreflexia with pain, fever, tachycardia, and abdominal distention.

Digital rectal examination reveals impacted feces palpated in the rectum. It is important to assess for size and consistency of the bolus as well as for the presence of blood. In the normal situation, the rectal ampulla remains empty. A fecal bolus does not pass beyond the rectosigmoid junction until the act of defecation commences.

Complications of fecal impaction can include acute or chronic bowel obstruction, mucosal ulceration, and hemorrhage.

After disimpaction, particularly in the recurrent setting, it is important to rule out an anatomic cause of obstruction. This may require proctosigmoidoscopy or a water-soluble contrast examination. Impaction may be associated with an anal or rectal stricture. The practitioner must assess for the presence of a tumor. Last, a deep mucosal ulcer may cause bleeding or infection as a result of fecal impaction. This is known as a *stercoral ulceration*.

## **TECHNIQUE**

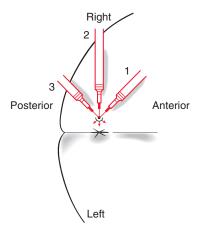

An attempt at *medical therapy* in an otherwise ambulatory patient is a reasonable first step. Careful administration of one or two Fleet enemas into the bolus to soften and hydrate the stool should be followed in 1 hour by the administration of a mineral oil enema to assist in passage of the softened stool. Soapsuds, hot water, or hydrogen peroxide enemas are discouraged because they may irritate the mucosa and result in bleeding. An alternative is an attempt at antegrade cleansing with either mineral oil or polyethylene glycol (PEG) solution lavage. The dose of mineral oil is 30 mL/10 kg orally in two divided doses for 2 consecutive days. The dose of PEG solution is 20 mL/kg daily for 2 consecutive days.

Manual disimpaction is required in most patients. This is best performed after a circumanal block of the anal musculature with local anesthetic. A four-quadrant field block allows for complete muscle relaxation and a painless disimpaction. Use 0.5% lidocaine drawn up in a 10-mL syringe. A 22-gauge, 1½-inch needle is used. Insert the needle all the way to the hub in each of the right, left, anterior, and posterior positions 1 cm away from the anal verge (Fig. 102-1). "Fan it out" in three directions at each of the injection sites, depositing a total of 2 to 3 mL of local anesthetic in each of the four sites as the needle is slowly withdrawn. The left decubitus position with hips and knees flexed to the chest is the most comfortable for the patient.

Gentle *digital dilation* of the sphincter is then performed as the fecal bolus is fragmented and extracted. A large, rigid proctoscope may be necessary to soften and break up stool residing higher in the rectum. After passing the rigid scope up to the fecal bolus, phosphate enema solution is passed through the scope to soften the stool. A long rigid aspirator is then passed through the scope to break up the softened stool and allow for evacuation. This process is repeated as many times as necessary to empty the bowel of stool.

Disimpaction may be facilitated by intravenous or intramuscular administration of a narcotic or anxiolytic. Early posthemorrhoidectomy impaction may be managed best in the operating room under general or regional anesthesia.

After disimpaction, it is prudent to institute a bowel habit program that includes laxatives, stool softeners, or enemas along with a regular time for evacuation to prevent reimpaction. PEG

**Figure 102-1** Technique of circumanal block with local anesthetic. Patient is in the left lateral decubitus position. Repeat the injection as shown, I cm from the anal verge, in all four quadrants (right, left, posterior, and anterior).

## 716 GASTROINTESTINAL SYSTEM PROCEDURES

solution can be useful to treat patients with chronic constipation prone to develop recurrent impaction.

# FLEXIBLE SIGMOIDOSCOPY

Michael B. Harper

The flexible sigmoidoscope has become a standard instrument in the primary care physician's office to detect and prevent colorectal cancer (CRC). Approximately 150,000 cases of CRC occur each year in the United States, with 55,000 deaths. It is the second-highest cause of cancer deaths in this country. The sigmoidoscope may be used to decrease morbidity and mortality of CRC either through early detection or by preventing it by removing precursor polyps. Well-designed, case-controlled studies have demonstrated the effectiveness of using sigmoidoscopy to screen for CRC, and sigmoidoscopy combined with annual fecal occult blood testing (FOBT) can be expected to yield an 80% reduction in mortality from CRC. In addition to screening for CRC, the sigmoidoscope is a valuable tool in evaluating symptomatic patients.

All major sources of guidelines for preventive medicine recommend screening for CRC, and physicians who fail to perform or recommend screening face medical-legal issues. Debate continues, however, regarding the best method of screening for this cancer. FOBT and sigmoidoscopy continue to be the most commonly used methods of screening for CRC in average-risk patients. Screening colonoscopy is becoming more popular, especially in high-risk patients, but direct evidence of mortality reduction is lacking. An extensive review of the literature (Frazier and colleagues, 2000) concluded that the best and most cost-effective method for CRC screening in average-risk patients was flexible sigmoidoscopy every 5 years, along with FBOT every year. In another screening model, colonoscopy once every 10 years was more cost effective than sigmoidoscopy every 5 years, but this model did not combine sigmoidoscopy and FOBT screening (Sonnenberg and colleagues, 2000). A recent study demonstrated that screening flexible sigmoidoscopy performed only once on people between ages 55 and 64 years, conferred a substantial (31% reduction in mortality) and long lasting protection from colorectal cancer (Atkin and colleagues, 2010).

Studies have concluded that patients will undergo whatever test their physician recommends. Unfortunately, in 2004 only 57% of adults in the United States had been screened by currently recommended methods. It is imperative for physicians to implement and encourage proper screening.

## **INDICATIONS**

• Screening: The American Society of Gastroenterology (ASGE), the American Cancer Society (ACS), the American College of Physicians (ACP), the National Cancer Institute (NCI), the American College of Obstetricians and Gynecologists (ACOG), the American Academy of Family Physicians (AAFP), and the United States Preventive Services Task Force (USPSTF) all recommend routine screening of not-at-risk patients 50 years of age and older for colon polyps and colon cancer. Note that no one is considered at "low risk" for screening purposes. The 2008 clinical summary of the USPSTF recommendations for screening for CRC are included in Table 103-1. (Also see "Colon Cancer Screening Options Vary" online at www.expertconsult.com.)

- Surveillance after previous polypectomy.
- Surveillance for effectiveness of treatment for ulcerative colitis/ Crohn's disease.
- Abdominal pain.
- Rectal bleeding (bright red or occult).
- Constipation or diarrhea.
- Persistent change in usual bowel habits.
- Unexplained weight loss, fever, or anemia.
- Suspected inflammatory bowel disease or antibiotic-associated colitis.
- Anorectal symptoms. (Note, however, that hemorrhoids alone are not an absolute indication for flexible sigmoidoscopy or aircontrast barium enema [ACBE] and must be put into the context of the entire patient history and examination. Medicare does not reimburse for an endoscopy procedure with the sole diagnosis of "hemorrhoids.")
- Evaluation of radiographic abnormality or to confirm a radiologic finding with a biopsy.

Although flexible sigmoidoscopy may be used for the initial evaluation of some complaints, it is limited by the amount of colon it can evaluate. Certainly with selected symptoms, if the sigmoidoscopy is negative, a more extensive work-up is still indicated. Thus, for many patients, obtaining a colonoscopy as the primary procedure may be more cost effective. On the other hand, availability and cost concerns may lead to sigmoidoscopy as the initial procedure of choice.

Because of redundant loops of sigmoid colon and because the insertion tube that is used for barium enema can obscure a lesion, flexible sigmoidoscopy (or, at the minimum, anoscopy) is generally needed along with ACBE if the entire bowel must be visualized. Individual circumstances dictate whether a flexible sigmoidoscopy alone or in conjunction with an ACBE is needed.

## **CONTRAINDICATIONS**

## **Absolute**

- Acute abdomen
  - Suspected perforation abscess
  - Peritonitis or intraabdominal sepsis
  - Diverticulitis
  - Bowel infarct
  - Fulminant colitis
- Severe cardiopulmonary disease
- Inadequate bowel preparation
- Uncooperative patient
- Marked bleeding disorder

## Relative

The following conditions require additional caution before performing flexible sigmoidoscopy:

Population	Adults Age 50 to 75 Years <sup>†</sup>	Adults Age 76 to 85 Years	Adults Older than 85 Years
Recommendation	Screen with high-sensitivity FOBT, sigmoidoscopy, or colonoscopy Grade: A	Do not screen routinely Grade: C	Do not screen Grade: D
	For all populations, evidence is insufficie colonography and fecal DNA testing	ent to assess the benefits and harms of sci Grade: I (insufficient evidence)	reening with computed tomographic
Screening Tests	High-sensitivity FOBT, sigmoidoscopy with FOBT, and colonoscopy are effective in decreasing colorectal cancer mortality.  The risks and benefits of these screening methods vary.  Colonoscopy and flexible sigmoidoscopy (to a lesser degree) entail possible serious complications.		
Screening Test Intervals	Intervals for recommended screening s Annual screening with high-sensitivity Sigmoidoscopy every 5 years, with h Screening colonoscopy every 10 years	FOBT nigh-sensitivity FOBT every 3 years	
Balance of Harms and Benefits	The benefits of screening outweigh the potential harms for 50- to 75-year-olds.		s because of the long average time
Implementation	Focus on strategies that maximize the number of individuals who get screened.  Practice shared decision making; discussions with patients should incorporate information on test quality and availability.  Individuals with a personal history of cancer or adenomatous polyps are followed by a surveillance regimen, and screening guidelines are not applicable.		
Relevant USPSTF Recommendations		use of aspirin or nonsteroidal anti-inflamm dation is available at http://www.preventiv	

FOBT, fecal occult blood testing.

<sup>1</sup>These recommendations do not apply to individuals with specific inherited syndromes (Lynch syndrome or familial adenomatous polyposis) or those with inflammatory bowel disease.

From U.S. Preventive Services Task Force: Screening for Colorectal Cancer: Clinical Summary of U.S. Preventive Services Task Force Recommendation. AHRQ Publication No. 08-05124-EF-4. Rockville, Md, Agency for Healthcare Research and Quality, October 2008. Available at http://www.ahrq.gov/clinic/uspstf08/colocancer/colosum.htm.

- Pregnancy
- Recent abdominal surgery
- Distorted pelvic anatomy
- History of pelvic irradiation
- Recent barium enema (if still passing barium because it can occlude the scope's port)
- When colonoscopy is indicated (such as in high-risk patients with inflammatory bowel disease who should receive a colonoscopy 8 years after the diagnosis was first made and every 5 years thereafter, for follow-up of polyps and colon cancer, and for patients with familial polyposis syndromes)

## **EQUIPMENT**

The flexible sigmoidoscope is available as either a fiberoptic endoscope or video endoscope. Although the fiberoptic scope has been the most commonly used version, the video sigmoidoscope is state of the art, using computer chip and video technology. The image from the tip of the scope is transmitted to a video monitor. This equipment facilitates videotape recording, sound narration, and other patient information storage.

The following basic equipment is necessary to carry out routine flexible sigmoidoscopy:

 60- to 70-cm-long submersible scope consisting of the body with controls (Fig. 103-1) and the shaft of the scope with tip and apertures (Figs. 103-2 and 103-3)

- Light source (most have air supply and wash bottle attached; Fig. 103-4)
- Suction apparatus (Fig. 103-5)
- Biopsy forceps (Fig. 103-6)
- Water-based lubricant (e.g., K-Y Jelly)
- 4 × 4 gauze pads
- Nonsterile gloves
- Shielded glasses
- Anoscope (Ives slotted anoscope preferred; see Chapter 98, Anoscopy)
- Basin of soapy water (immediately on completion of the procedure, suction water through the scope, then place the scope in the basin)
- Formalin jars
- Disinfecting cleanser
- Nursing assistant (to assist with equipment and procedure)
- Video unit and monitor (for video endoscopes only)

Figure 103-1 Control head and body of the fiberoptic sigmoidoscope.

<sup>\*</sup>This document is a summary of the 2008 recommendation of the U.S. Preventive Services Task Force (USPSTF) on screening for colorectal cancer. ## PREPROCEDURE PATIENT PREPARATION

A good history (present and past) is essential before performing any procedure. Not only should the patient's overall medical risk status be determined, but the risk for CRC and any associated symptoms must be assessed to ensure that flexible sigmoidoscopy is indeed the proper procedure and that there are no contraindications to performing it.

Flexible sigmoidoscopy in most patients is easily performed in less than 15 minutes. However, for some patients the very thought of a tube in the rectum provokes anxiety, apprehension, and reluctance. This makes it necessary for the clinician to reassure the patient and allay apprehension and anxiety with a thorough explanation. Use simple words with the aid of charts and figures. Explain the procedure to be performed, why and how it will be done, and the possible complications. The components of this patient education process include the following:

- 1. Bowel cleansing instructions (usually two enemas; see the sample patient education handout online at www.expertconsult.com)
- 2. Equipment used
- 3. Anatomy of the colon
- 4. Explanation of procedure
- Discomfort experienced during the procedure ("crampy distention," especially at the second curve around 40 cm and with insufflation of air)

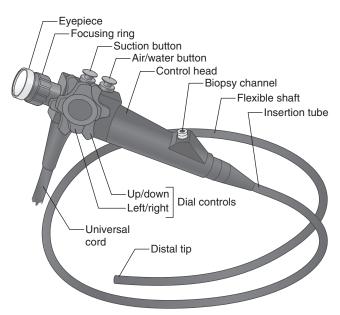

Figure 103-3 Schematic diagram of a fiberoptic sigmoidoscope.

Figure 103-4 Light source with air supply.

- 6. Complications that are remotely likely (e.g., perforation, bleeding)
- 7. Possible diseases likely to be detected
- 8. Biopsy technique, if needed
- 9. Whether photography or videotape will be used
- 10. Management of any findings
- 11. The need to continue all prescribed medications

It is highly advisable to have the patient sign the informed consent form for this procedure after reading the patient information materials. (See the sample patient education handout and consent form online at www.expertconsult.com.)

Flexible sigmoidoscopy is well tolerated by the vast majority of patients. Mild analgesia or sedation, whether given orally or intramuscularly, is rarely needed. Oral diazepam or ibuprofen can be used as needed in the individual situation. Atropine 0.5 mL intramuscularly can be given for those who have a tendency to faint or experience vasovagal symptoms.

## **Patient Bowel Preparation**

Simple enemas (tap water, Phospho-Soda) administered until clear fluid is passed is the only requirement. This usually entails two enemas (occasionally three) 30 to 60 minutes before the procedure. Patients are allowed to take their medications and eat normally. If the patient tends to be constipated, a laxative should be given the day before the procedure. Keeping the regimen simple is more likely to ensure compliance.

In one study (Sharma and Chockalingham, 1997), two Fleet enemas given on arrival to the endoscopy suite were compared with one bottle of magnesium citrate and two Dulcolax tablets the evening before the procedure. Both patients and endoscopists preferred the oral method. Another study (Manoucheri and colleagues,

Figure 103-5 Suction apparatus.

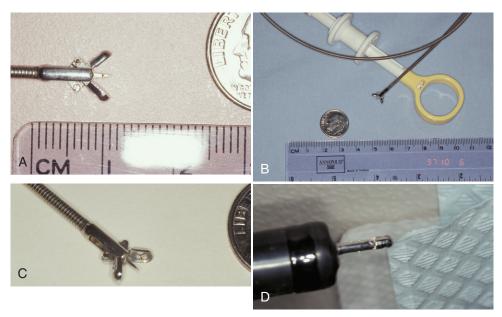

Figure 103-6 Biopsy forceps. A, Relative size of forceps. B, Control handle. C, Stabilizing needle. D, Biopsy forceps protruding from end of scope, closed on a piece of paper. (Courtesy of John L. Pfenninger, MD, The Medical Procedures Center, PC, Midland, Mich.)

1999) showed no difference in results comparing four bowel preparation regimens.

## **Antibiotic Prophylaxis**

Antibiotics for subacute bacterial endocarditis prophylaxis are no longer recommended for lower endoscopy procedures with or without the performance of biopsies, even in high-risk patients (see Chapter 221, Antibiotic Prophylaxis).

## **TECHNIQUE**

A specific terminology has developed around the procedure of flexible sigmoidoscopy. Box 103-1 summarizes this "language" that must be understood before learning the procedure.

- 1. Before beginning the procedure, all functions of the endoscope must be checked. The light source should be turned on and clarity of view confirmed. White balance must be performed for videoscopes. The "button" to insufflate air and the water button are the same (see Fig. 103-2). Just covering the air/water button introduces air, whereas pushing it down all the way ejects a small amount of water to clean the lens. This button is the one closest to the patient. The second button, closer to the eyepiece, is for suction. Remember: the button closest to the patient puts things in and is usually colored blue, the button closest to the endoscopist "sucks" things out and is usually colored red. Air function is confirmed by inserting the scope tip in water and seeing bubbles when the air port is occluded. Suction is confirmed by suctioning a small amount of water through the endoscope. Tip deflection is checked by rotating both control wheels fully in both directions while observing and feeling for free movement. After checking all functions, the fiberoptic unit may be turned off temporarily. Many video endoscopes have to be white balanced each time they are turned off, so leaving them on is preferable.
- 2. If sedation is to be used, record the patient's temperature, pulse, respiration, blood pressure, and results of heart/lungs auscultation and abdominal examination.
- 3. Position the patient in the *left lateral Sims' position* (see Chapter 97, Clinical Anorectal Anatomy and Digital Examination, Fig. 97-2).
- 4. The endoscopist and assistant should wear *nonsterile gloves* on both hands. Double glove the right hand. (Remove the extra

- glove after the tip has been lubricated, the rectal examination performed, and the scope initially inserted.) Place the body and shaft of the scope on the cart. Lubricate the distal 3 to 4 cm of the shaft tip with K-Y Jelly (avoid the lens). Notice where the dials are positioned when the shaft is completely straight.
- 5. Separate the gluteal folds laterally with the hands to expose the anal area and the anal aperture for inspection. *Perform a digital rectal examination* with K-Y Jelly or lidocaine ointment to ensure there is no obstruction or stool in the anal canal. In male patients, examine the prostate carefully. A painful examination should alert the endoscopist to a fissure, proctitis, or colitis. The examination is uncomfortable but should not be painful if it is done gently. The digital examination helps to relax the sphincter and lubricates the anal canal. (See Chapter 97, Clinical Anorectal Anatomy and Digital Examination.)
- 6. Now hold the body of the scope in your left hand (Fig. 103-7). Hold the end of the scope shaft in the right hand, and, with the index finger alongside and stabilizing the very end, gently insert it. Hold the tip at an oblique angle pointing posteriorly, and stretch the sphincter as the tip is slipped into the anal canal. The shaft tip can be blindly inserted 10 to 20 cm. Stop when resistance is felt. Remove the second glove on the right hand.
- 7. With the distal 10 cm or more of the scope in the anal canal, switch on the light source, air, and suction, if these had been turned off. Check the view in the eyepiece or on the video screen.
- 8. Keep holding the body of the scope in your left hand so that your thumb controls the large dial and your index finger controls the suction, irrigation, and air valves. Hold the shaft and advance it with your right hand, which is also available to control the small dial. Alternatively, an assistant may advance the scope, and you may use your right hand to manipulate the dials. The assistant must be cautioned never to advance the scope against resistance and to advance the scope only when told to do so. This latter method is easier and faster for some physicians, but solo operation may allow better coordination of movements of the shaft and deflecting tip. Use the technique that accomplishes the procedure in the fastest manner with minimal patient discomfort.
- 9. Insufflation advance technique
  - Air is needed to maintain patency of the lumen and to obtain a clear view adjacent to the tip and a few centimeters beyond.
     Remember, the air button and water button are the same.

## Box 103-1. Flexible Fiberoptic Sigmoidoscopy Terminology

**Tip:** Distal end of the shaft of the sigmoidoscope (see Fig. 103-2).

Dials: Tip control knobs. Large inner dial moves the tip up and down. Small outer dial moves the tip left and right (see Fig. 103-3). The clinician should note the neutral position for future reference when in the bowel.

**Biopsy channel:** The slot through which the biopsy forceps and also the brush wire are passed through the body and shaft of the scope (see Figs. 103-1, 103-3, and 103-6D).

Suction control button (nearest the operator): When pressed all the way down, this button allows the suction to operate continuously.

Air insufflation/lens cleaner (water) button (farthest from the operator): This button has a small opening that can be occluded to allow air to pass into the colon continuously (see Fig. 103-3). Pressing the button completely down will squirt water across the lens at the tip and will clear away debris.

Suction, air, and water connection ports: The location of tubes connecting on the bottom of the handpiece that go to suction, air, and water sources.

Slide-by: A technique of passing the flexible sigmoidoscope where the advancing tip of the scope is advanced proximally into the colon without complete visualization of the lumen. As the scope advances, the practitioner sees the vascular mucosa "slide by." This maneuver is often unavoidable but should be used very sparingly, and the scope should be advanced only 5 to 10 cm. If the lumen is not fully visualized or if pressure, resistance, or pain is encountered, the clinician should pull back and look again for the lumen.

**Pullback:** Withdrawing the shaft of the scope to diminish or eliminate whiteout, redout, stretching, or looping.

One-on-one: As the scope is advanced into the rectum, there is an equal advance of the scope into the segment of colon (versus just stretching the colon without true advancement).

**Redout:** The tip of the scope lies flat against the mucosal surface, resulting in a red appearance through the lens.

Whiteout: The mucosal surface is stretched by the tip of the scope pressing against the mucosal surface. The vessels are thus blanched, giving a white appearance.

**Tip deflection:** The tip can be directed in four directions by rotating the dials: up ("north"), down ("south"), left ("west"), and right ("east"). The deflection should always be moderate and gentle. Alternatively, the head of the scope itself can be rotated right and left to turn the tip to the right or left after being flexed up or down.

Dithering: A to-and-fro advance-and-withdrawal process performed with an amplitude of 5 to 6 cm and repeated every 2 to 4 seconds, coupled with a clockwise torque on the shaft on the pullback motion and a counterclockwise torque on the inward motion. This maneuver helps straighten the sigmoid colon, allowing it to compress like an accordion over the scope (see Fig. 103-9).

**Jiggling:** A to-and-fro, 5- to 6-cm inward-and-outward motion of the shaft performed every 2 to 4 seconds. It helps in the visualization of a segment of colon and can often aid scope advancement (see Fig. 103-10).

**Alpha maneuver:** Used only after much practice by the experienced endoscopist to assist in shortening or pleating the segments of the colon (see Fig. 103-11 and text for explanation).

**Torquing:** Twisting the distal shaft of the scope by rotating the head either clockwise or counterclockwise.

**Retroflexion:** Maximally flexing the tip of the scope, enabling it to look back on itself. This is often used to evaluate the rectum.

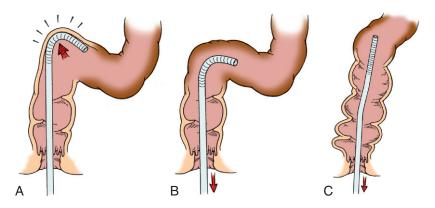

Just covering the button introduces air, whereas pushing it down all the way diverts air into the water bottle and ejects a stream of water across the lens to clean it. A sufficient amount of air must be used to expand the bowel, but too much air may cause cramping or, in extreme cases, even

**Figure 103-7** Control head of the sigmoidoscope should be held in the left hand so that the thumb rests on the up/down control dial and the index finger can regulate the suction and air/water buttons. (Courtesy of Michael B. Harper, MD.)

perforation. Excess air also lengthens the bowel and may cause sharper bends. Use patient comfort as a guide. With a clear view ahead, gently advance the shaft forward. The scope is usually advanced up to 15 to 18 cm without difficulty. There are three "valves" that are encountered in the rectum: the valves of Houston. These are semilunar in shape, are not really "valves," and are located 6, 9, and 12 cm from the anal verge. Negotiating advancement into the rectosigmoid can be hampered by these folds, and the tip needs to be deflected away from the fold and toward the lumen to avoid redout or whiteout. The clinician can get "lost" in the vast arena of the rectal vault and have difficulty in locating the rectosigmoid orifice. This is more likely if too much air is insufflated, which causes the ampulla to expand upward.

- There is always a question of how much air to use. The answer: enough! Generally, as long as the patient is not sedated, he or she will tell if too much pressure is being generated. Some clinicians are too timid and will never see the lumen if "enough" air is not used.
- At this stage, you do not need to attempt to visualize the entire circumference of the bowel. Rather, the primary goal is to insert the scope as far as possible. Deflect the tip only enough to clearly see the direction of the lumen. By minimizing tip deflection the force of insertion will be directed more toward the tip and the tendency to form a loop is decreased. It is critical that the complete circumference of the bowel be closely inspected, lest a lesion be missed, but this is usually performed during withdrawal of the scope.

**Figure 103-8** Method of advancement at the rectosig-moid junction. Various maneuvers are needed. **A,** The scope is entering into the anus, but the view from the end of the sigmoidoscope is not changing. There is no "one-on-one" advancement; rather, the segment of colon is merely being stretched, often causing pain. **B,** Try the simple hook-and-pullback technique initially. **C,** Pulling back on the scope causes an accordion effect and straightens the curve.

- It is ideal if the scope is passed only when the lumen is seen, but, practically speaking, the slide-by method is used commonly and is safe as long as the scope passes easily and the patient (unsedated) is not feeling excessive pain (see Box 103-1). To perform this maneuver, first determine the direction of the lumen. If you do not see the lumen it is easily located by moving the controls toward neutral, then releasing the controls and slowly withdrawing the scope (this is a basic maneuver to find the lumen with any gastrointestinal endoscopy). The lumen will usually come into view after withdrawing only a few centimeters. Once the lumen direction is determined, deflect the tip toward the lumen and gently advance the scope while watching for movement of mucosa. Continue to advance as long as the patient is comfortable and you see mucosal movement. The lumen should come back into view after advancing a few centimeters. Stop the slide-by if you have a redout or whiteout, or cause excessive patient discomfort.
- 10. Advancing the scope into the sigmoid and descending colon may require using different maneuvers in the presence of redundancy, adhesions, angulation, and loops. At times, especially in young persons, the scope can be advanced all the way up to the transverse colon without any difficulty. In older patients, especially those who have had abdominal or pelvic surgery, the presence of adhesions may make further advancement difficult. The rectosigmoid junction is at 15 to 18 cm. Advancement may be hampered here by the angulation of the bowel toward the left into the left iliac fossa. The length of the sigmoid itself varies from 20 to 45 cm. Certain maneuvers—individually or in combination—can then be attempted to advance the scope through the descending colon and into the distal portion of the transverse colon.
  - Advancement by hook, rotation, and pullback. When the scope will not advance, deflect the tip of the shaft 30 to 90 degrees behind a mucosal fold (Fig. 103-8) and withdraw the shaft 5 to 10 cm, pulling the segment of the colon downward, twisting the head of the scope to the right, and creating a pleating and straightening-out effect. Repeat this maneuver several times as needed to achieve the desired goal of compressing the bowel over the shaft of the scope, much like an accordion. It should be done very gently with minimal (if any) resistance. When you cannot go forward, flex the tip down, torque to the right, and withdraw. It is a difficult concept to master, but to go forward you must pull back, as noted.
  - Dithering-torque maneuver (Fig. 103-9). The dithering-torque maneuver is a to-and-fro advance-and-withdrawal process performed with an amplitude of 5 to 6 cm every 2 to 4 seconds. It is coupled with a clockwise torque of the shaft of about 45 to 60 degrees on the pullback motion and a counterclockwise torque on the inward motion. This process "accordionizes" the colon onto the shaft of the scope, thereby shortening the colon and enabling a larger length of the colon to be traversed and examined. Gentle tip deflection of

- 30 degrees with the torque motion is recommended. The *clockwise* torque tends to loop the sigmoid, whereas the *counterclockwise* torque tends to straighten it. This is an effective maneuver in shortening the sigmoid, and it is of greatest use in a redundant sigmoid colon. Excessive tip deflection can become a hindrance to further advancement; therefore it should be kept to the minimum to maintain visualization of the lumen. If the tip needs greater deflection at the moment, it should be straightened soon after the lumen is located.
- Jiggling is merely an in-and-out motion deflecting the tip slightly, trying to get the scope to advance. In performing flexible sigmoidoscopy, it is best to keep the scope moving in some manner to maximize the opportunity of seeing the lumen (Fig. 103-10).
- Alpha maneuver (for experienced endoscopists). Advance the scope into the sigmoid. At about 25 to 30 cm, deflect the tip to visualize the lumen anteriorly, and then torque the shaft counterclockwise about 145 to 180 degrees (Fig. 103-11A). This swings the proximal part of the sigmoid over the distal part, so that the sigmoid colon forms a loop over itself (Fig. 103-11B and C). Here, minimally deflect the tip to locate the lumen and then straighten it as much as possible. Further advancement of the scope will lead it into the descending colon. If resistance is encountered, rotate the shaft clockwise and withdraw to "accordionize," or shorten, the sigmoid (Fig. 103-11D). The shaft can then be advanced into the descending colon, to the splenic flexure (see Fig. 103-12D). The alpha maneuver is rarely needed but may be necessary in the redundant bowel. It should be used only by the experienced endoscopist.
- 11. Opinions vary as to whether *changing patient position* will improve visualization or aid in advancement of the scope. Many

**Figure 103-9** Dithering maneuver. Rotate counterclockwise when withdrawing and clockwise when inserting. See text for details.

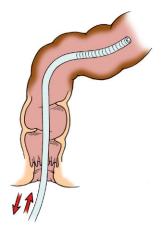

Figure 103-10 Jiggle maneuver. See text for details.

will roll patients onto their backs. Try it if other maneuvers do not work.

12. Once past the "second curve," the scope is generally advanced with minimal manipulation into the descending colon by jiggling, hooking, and pulling back; simply maintaining mild inward pressure on the shaft usually suffices.

The area of the splenic flexure can often be recognized by the bluish hue superiorly, which represents the transmitted vascularity of the spleen sitting on the colon exteriorly. The colon takes a turn anteriorly and to the patient's right at this point, and the triangular folds of the transverse colon can be identified easily (see Fig. 103-12E).

13. Inspection: Withdrawal of the scope is easy but probably the most important part of the procedure. Using a combination of tip deflection and torquing in both directions, gradually withdraw the shaft, visually inspecting the entire circumference of the intubated colon. Pay careful attention to all areas of the mucosal

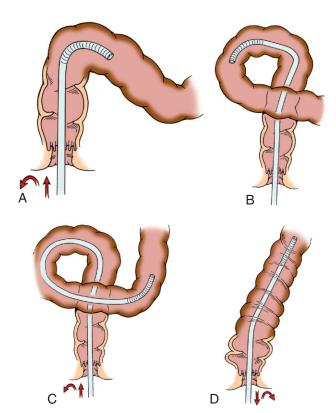

Figure 103-11 A-D, Alpha maneuver. See text for details.

surface, particularly behind mucosal folds. Make note of diverticula and any masses. (See the Biopsy section, later.) If any segment is not seen completely, advance and withdraw again. Continue withdrawing until the rectum is reached.

- 14. Retroflexion: The anal canal and distal rectum must be inspected thoroughly in one of two ways: by using an anoscope or by completely deflecting the sigmoidoscope tip to look back on itself (i.e., retroflexion; see Fig. 103-12N through Q). Either procedure is performed after completing the examination of as much proximal bowel as possible with the sigmoidoscope. The sigmoidoscope can simply be withdrawn completely and the anal canal examined with the anoscope. Or, to accomplish the retroflexion maneuver, withdraw the endoscope to the anal verge, then gently advance the scope about 10 to 12 cm while simultaneously turning both controls counterclockwise to full deflection. You will be looking back onto the shaft of the scope and will see it passing through the anal canal. By torquing the shaft you can perform a 360-degree visual inspection of the distal rectal vault and the inner aspect of the anal canal and papillae to detect masses and hemorrhoids (although these are much better appreciated with an Ives slotted anoscope). After completing the examination, straighten the tip and withdraw it very slowly. Grasp the tip of the scope as it slips out of the anus so that it does not drop on the table, damaging its delicate construction.
- 15. Remove all the air: You may do this before completely removing the scope or reinsert the scope 5 to 6 cm. Apply intermittent suction and use a to-and-fro motion with rotation to prevent the mucosa from being drawn into the suction port, thus occluding it (see following Step 16). After the patient indicates that the air is gone, remove the scope and immediately draw soapy water through the suction port. Also, occlude the air port to "blow out" any accumulated debris. The latter two steps will enhance cleaning and preserve proper functioning of the scope.
- 16. Removing colonic fluid and air. Do not attempt to suction any solid material through the scope. The channels are extremely small and are easily plugged. When suctioning (button closest to the endoscopist), intermittently push the button all the way down while instilling air and moving the scope back and forth a few centimeters. Constant suctioning at one position will suck mucosa into the scope, causing what appears to be a polyp ("suction polyp" or "pseudopolyp"). This artifact should disappear or flatten if the bowel lumen is expanded with air but may temporarily leave a circular mark on the mucosa. Keeping the scope in motion and compressing the suction button intermittently will help avoid unnecessary biopsy procedures and confusing findings.
- 17. The scope should be cleaned and disinfected as soon as possible after the procedure is completed (see later discussion).

## **Biopsy**

There are many opinions about when and if biopsies should be obtained during flexible sigmoidoscopy. Some points of view with countering arguments include the following:

- Primary care physicians should not perform a biopsy on any lesion. (Counter: The biopsy technique is simple and virtually without complication when only the cold [without electrocautery] biopsy forceps are used. It samples only 2 to 3 mm of the mucosa, and unless the tissue is pulsating, ulcerated, or inside a diverticulum, perforation is almost impossible.)
- It is useless to obtain a biopsy sample because the colonoscopist will need to remove the polyp anyway. (Counter: If the biopsy result shows only a hyperplastic polyp [see Fig. 103-12H], there is no need for colonoscopy. Documentation of an abnormality aids in categorizing the patient's risk status and reinforces the physician's rationale for the patient to have the often-resisted colonoscopy performed. It also confirms the diagnosis for the colonoscopist and mandates that the lesion be found.)

- Do not perform a biopsy on small polyps (<5 mm). (Counter: It is precisely these lesions that are difficult to diagnose accurately with an endoscope, so they require biopsy to determine if they are adenomatous and thus require full colonoscopy. Even very small, "diminutive" polyps, that appear to be benign, can be advanced adenomas [villous histology or high-grade dysplasia], and cause the patient to be in the same high-risk group as patients with larger adenomatous polyps [Schoen and colleagues, 2006].)
- Performing a biopsy may increase malpractice insurance. (Counter: Not doing it may miss a crucial diagnosis. In general, premiums are not increased for this very-low-risk diagnostic procedure. If the lesion is not sampled and the colonoscopist cannot find it on a later examination, it may prolong the procedure, and the patient's actual status remains unknown.)
- Performing a biopsy provides pathology feedback to the endoscopist, which increases the learning curve for clinical diagnoses in the future.

**EDITOR'S NOTE:** It is our practice to perform a biopsy on essentially all nonvascular lesions. No complications have been encountered. If it does not look like the mucosa on the inside of your mouth, if it is not pulsating, if you are not inside a diverticulum, and if you do not know what it is, perform a biopsy!

#### **Precautions**

The following are some caveats regarding biopsy:

- A vascular lesion (especially if pulsating!) may best be left for later biopsy under more controlled situations.
- Do not perform electrosurgical removal of a polyp except in a fully prepared bowel (bowel gases in the colon can explode).
- After the procedure, ensure and document that all bleeding has stopped.
- Document the location from which each polyp was removed and, except for small polyps in close proximity to each other, place each polyp in a separate specimen container.

## Biopsy Technique

Position the scope tip is so the selected biopsy site is 2 to 4 cm away and at 6 o'clock on video endoscopes or opposite the black triangle on fiberoptic scopes. Pass the closed forceps down the biopsy channel while keeping the lumen in view to avoid risk of damaging the bowel wall. The assistant should maintain gentle pressure on the forceps controls to keep the jaws closed. Excessive closing pressure causes the forceps to become stiff and can make passage through a deflected tip difficult or damage the endoscope. Once the forceps tip has emerged from the distal tip of the scope, ask the assistant to open the jaws of the forceps. Advance the open forceps against the desired site and ask the assistant to close the jaws. Gently pull out on the forceps to "tent" the mucosa and confirm the desired site is in the jaws, and then sharply withdraw the forceps to remove the tissue by applying a quick jerk to the line. The biopsy sample is placed in formalin and the site observed for bleeding. Occasionally, a second or even a third biopsy sample of the lesion may be indicated (see Fig. 103-5). If the forceps have a central needle, a second biopsy can often be obtained on a single passage.

## **FINDINGS**

See Figure 103-12.

- Polyps (iatrogenic "suction polyps," hyperplastic, and adenomatous [tubular, tubulovillous, and villous adenomas])
- Cancer
- Inflammation (inflammatory bowel [Crohn's and ulcerative colitis], antibiotic-associated colitis)
- Diverticula
- Melanosis coli
- Arteriovenous malformations
- Foreign bodies
- Condylomata
- Hemorrhoids (internal)

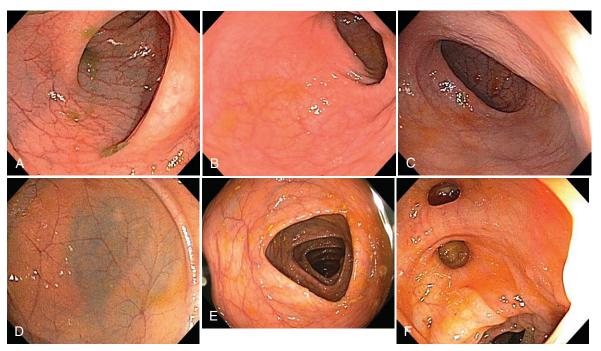

Figure 103-12 Normal and abnormal findings during sigmoidoscopy. A, Semilunar valves of Houston. B, Rectosigmoid area. C, Sigmoid colon. D, The splenic flexure. The spleen projects a cyanotic hue through the colon wall. E, The transverse colon with characteristic triangular appearance of the folds. F, Diverticulosis.

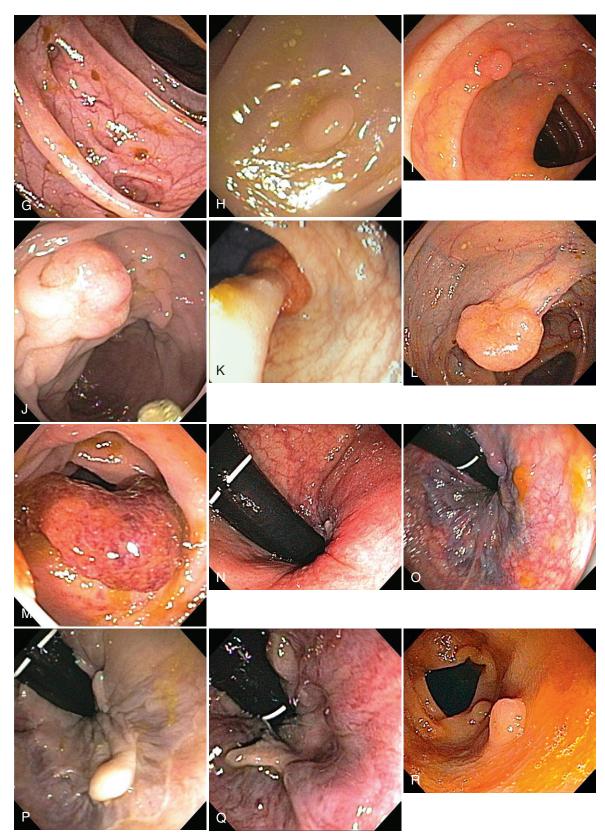

Figure 103-12, cont. G, Multiple diverticula. H, Small polyp that was hyperplastic on biopsy. I, Small adenomatous polyp at the splenic flexure. The scope is looking across the transverse colon, which can be identified by its triangular shape. J, Pedunculated polyp. K, Another pedunculated polyp. L, Large sessile polyp in the sigmoid colon. M, Large colon mass that was a cancer on biopsy. N, The retroflexion maneuver in a normal rectum performed just before the scope is totally removed. Note that the scope is turned upon itself in a "big U" and the view is of the scope coming through the anus. Note the normal vascular pattern of the bowel. O, Internal hemorrhoids seen on retroflexion. P, Hypertrophied anal papilla. Q, Hypertrophied papilla along the dentate line. Internal hemorrhoids also present. R, Everted diverticulum, confirm by probing with closed forceps, do not snare these. (K, Courtesy of John L. Pfenninger, MD, The Medical Procedures Center, PC, Midland, Mich.)

## **Documentation**

It is important that all findings be noted and documented. A comment should be made on each of the following: scope used, distance inserted by anatomic location and centimeters, quality of preparation, patient tolerance, vascular and mucosal patterns, size of any polyps identified and location where they were found, ease of biopsy and control of any bleeding, final impression, and follow-up recommendations (Fig. 103-13).

## Significance of Various Polyps

It is beyond the scope of this chapter to provide an extensive discussion of the significance of various polyps. More information is included in Chapter 100, Colonoscopy. In brief, all adenomatous (neoplastic) polyps (tubular, tubulovillous, and villous lesions) have a malignant potential. Recent articles document the reduction of CRC if all neoplastic polyps are removed. Most experts agree that hyperplastic polyps have little prognostic significance. Colonoscopy

is not recommended for hyperplastic polyps, whereas it is essential with neoplastic polyps.

## **COMPLICATIONS**

- Bowel perforation (very rare, <1:20,000)
- Bleeding (more likely if a biopsy sample was obtained, but still very uncommon)
- Abdominal distention and pain, often due to the insufflated air (be sure it is all removed)
- Infection (although very rare, inadequate cleaning of scopes can transmit disease)
- Vasovagal symptoms
- Missed disease

Complications from flexible sigmoidoscopy are very rare. Their incidence is higher in patients with previous bowel or pelvic surgery, or irradiation. These patients have more adhesions, which tether the bowel to a fixed position, predisposing it to perforation. If the scope is advanced blindly, without seeing the lumen, the risk of perforation also increases. However, at times this is necessary and safe as long as no resistance is felt and the patient is not overly uncomfortable.

Care must be taken in the presence of diverticulosis. The mouth of the diverticulum can be interpreted as the bowel lumen, and if the scope is inserted, perforation can occur.

Missed disease can occur if the endoscopist is unable to adequately insert the endoscope. This problem occurs more commonly in women and elderly patients (Walter and colleagues, 2004). Disease in the rectum can also be missed if retroflection or anoscopic examination is not performed.

## CLEANING AND DISINFECTION OF SCOPES

The various instrument representatives will detail the exact cleaning mechanism for each brand of scope. Tremain and colleagues (1991) present an excellent review, and reading of this article is strongly encouraged. Jackson and Ball (1997) also summarize the essential steps in disinfecting scopes. It is essential that the clinician's staff pay meticulous attention to cleaning directions for the scope. The orifices are very small and a small amount of debris can prevent optimal functioning.

## POSTPROCEDURE PATIENT EDUCATION

After completion of the procedure, explain the following to the patient:

- Findings.
- Where the biopsy samples have been taken from and the necessity for pathologic evaluation.
- Further management or referral, and future surveillance plans.
- Implications of the presence of cancer or polyps for the patient's siblings and children.
- Necessity of reporting any excessive bleeding or abdominal pain.
- Reinforce that proximal lesions are certainly possible and that if any symptoms develop (or persist if present), then further evaluation is necessary.
- Primary prevention methods include the possible use of a nonsteroidal anti-inflammatory drug (NSAID), not smoking, and a high-bulk, low-fat diet with at least five helpings of fruits and vegetables a day. A multivitamin a day (folic acid and vitamin D), estrogen use, and statins may also reduce the incidence of CRC. The USPSTF recommends against the routine use of aspirin and NSAIDs to prevent CRC in individuals at average risk for CRC since side effects may outweigh the benefits.

## **CPT/BILLING CODES**

- 45330 Sigmoidoscopy, flexible fiberoptic; diagnostic with or without collection of specimen by brushing or washing
- 45331 Sigmoidoscopy with biopsy, single or multiple
- 45332 Sigmoidoscopy with removal of foreign body
- 45333 Sigmoidoscopy with removal of polypoid lesion(s) by hot biopsy forceps or bipolar cautery
- 45334 Sigmoidoscopy with control of hemorrhage (e.g., electrocoagulation)
- 45338 Sigmoidoscopy with removal of polypoid lesion(s) by snare technique
- 45339 Sigmoidoscopy with ablation of tumor or mucosal lesion not amenable to removal by hot biopsy, or snare technique
- 46600 Anoscopy; diagnostic (separate procedure)

Medicare will pay for *screening* flexible sigmoidoscopy after 47 months have passed since the flexible sigmoidoscopy or barium enema. The code GO104 should be used. If a biopsy is taken, the code 45331, not the "G" code, should be used.

## **ICD-9-CM DIAGNOSTIC CODES**

- 078.11 Condyloma
- 153.2 Cancer, colon—descending, left
- 153.3 Cancer, colon—sigmoid
- 154.1 Cancer, rectum
- 154.2 Cancer, anus
- 153.9 Cancer, colon, unspecified
- 211.3 Benign neoplasm, colon
- 211.4 Benign neoplasm, rectum/anus
- 455.0 Internal hemorrhoids
- 455.2 Internal hemorrhoids, bleeding
- 555.1 Crohn's disease—colon
- 556.9 Ulcerative colitis
- 558.1 Radiation colitis
- 558.9 Colitis, nonspecific
- 562.10 Diverticulosis without hemorrhage
- 562.12 Diverticulosis with hemorrhage
- 562.13 Diverticulitis with hemorrhage
- 564.00 Unspecified constipation
- 564.1 Irritable colon
- 565.0 Anal fissure
- 566 Perirectal abscess
- 569.0 Anal polyp
- 569.3 Anal hemorrhage
- 569.42 Anal pain
- 569.82 Ulcer, colon
- 569.84 Angiodysplasia, colon
- 578.1 Melena
- 578.9 Gastrointestinal hemorrhage, hematochezia
- 783.21 Weight loss
- 787.4 Hyperperistalsis
- 787.6 Stool incontinence
- 787.99 Tenesmus
- 789.00 Abdominal pain
- 793.4 X-ray abnormality, gastrointestinal tract
- V10.05 Personal history colon cancer (not primary diagnosis)
- V16.0 Family history colon or other GI cancer (not primary diagnosis)
- V18.51 Family history colon polyps
- V18.59 Family history other gastrointestinal disorders (not primary diagnosis)

Medicare-covered codes include history adenomatous polyps (V6700, V12.72), malignant and benign gastrointestinal tract neoplasm (150.0–154.8, 159.0, 159.8, 211.0–211.4), and ca-in-situ

(230.1–230.7, 235.2, 235.5, 239.0); infectious gastrointestinal diseases and colitis (555.0–556.9, 558.2–558.9), ischemic lesions (557.0–557.1), other diseases (560.0–566, 568.0–569.9, 619.1, 759.6, V12.70); hematochezia, melena, change in bowel habits, abdominal pain, abdominal or pelvic mass, occult blood, anemia, abnormal x-ray examination, personal history of gastrointestinal cancer.

# VIDEO CAPSULE ENDOSCOPY\*

Matti Waterman • Edward G. Zurad • Ian M. Gralnek

Video capsule endoscopy (VCE) of the small bowel is one of the major advances in small bowel imaging in the last several years. Compared with other existing imaging modalities, VCE has been demonstrated to have the highest yield in the diagnosis of gastrointestinal (GI) hemorrhage of obscure origin, iron-deficiency anemia (IDA), small bowel tumors, suspected or early Crohn's disease (CD), and several other medical conditions involving the small intestine. This relatively easy-to-use, minimally invasive procedure, requiring limited or no patient preparation and no sedation, has acquired enormous worldwide popularity since its clearance by the U.S. Food and Drug Administration (FDA) in 2001. The original wireless capsule endoscope was the M2A small bowel capsule (now called Pillcam SB; Given Imaging, Ltd., Yoqneam, Israel). In September 2007, the FDA cleared the Olympus Corporation's EndoCapsule. Other companies have also started to produce small bowel capsule endoscopes, including the MiroCam from South Korea and the OMOM capsule from the People's Republic of China. Neither of those products has FDA clearance for use in the United States. In 2008 it was estimated that over 600,000 capsules have been ingested worldwide and over 600 scientific articles regarding VCE have been published. Its growing popularity and simplicity make VCE a viable option in the office work-up of patients with suspected small bowel disease by primary care physicians. In this chapter, we discuss indications for the procedure, the procedure itself, the image reviewing process and interpretation of common findings, patient instructions, and procedure-related complications and how to minimize them. Capsule endoscopy for the esophagus and the colon is still not widely accepted and practiced, and therefore these procedures are not discussed.

## **INDICATIONS**

Indications for VCE of the small bowel are listed in Box 104-1.

# **Obscure Gastrointestinal Bleeding**

The source of GI bleeding remains unidentified in approximately 5% of patients and is thus referred to as *obscure*. Obscure GI bleeding may be overt, as evidenced by clinical signs (melena or hematochezia), or occult and manifested as positive fecal occult blood testing or IDA. By definition, obscure GI bleeding occurs when esophagogastroduodenoscopy (EGD) and colonoscopy are negative. In such cases, further work-up is required. The role of VCE in obscure GI bleeding has been validated in two meta-analyses and is outlined in Figure 104-1. In patients presenting with IDA, VCE has a less validated role (Fig. 104-2). As has been validated in the aforementioned meta-analyses, VCE is the most sensitive diagnostic modality and is considered the first line in the diagnostic work-up for obscure GI bleeding. Figure 104-3 shows an example of bleeding in the small bowel as captured by the Pillcam.

#### Crohn's Disease

Crohn's disease is an idiopathic inflammatory disease involving the small bowel in approximately 75% of cases. Because no diagnostic gold standard exists, the diagnosis of CD in the small bowel is based on clinical, endoscopic, radiologic, and histologic findings. However, available diagnostic modalities are neither sensitive nor specific. As a result, appropriate drug therapy may be delayed. Furthermore, available endoscopic procedures (e.g., push enteroscopy) fail to visualize the entire small bowel distal to the ligament of Treitz; thus, significant small bowel involvement may be missed. VCE has a role both in diagnosing suspected CD (Fig. 104-4) and in determining the extent of small bowel involvement in CD. VCE also has been shown to be more sensitive than other imaging modalities in detecting small bowel mucosal breaks and thus is very helpful in diagnosing early CD (Fig. 104-5) and in assessing mucosal healing after drug treatment and disease recurrence after surgery.

#### **Small Bowel Tumors**

The advent of VCE has resulted in a major shift in the diagnosis of small bowel tumors (Fig. 104-6). In the past, small bowel tumors were usually diagnosed only during the work-up of persistent abdominal pain or when obstructive symptoms appeared. Today, approximately 80% of small bowel tumors that are detected by VCE are from referrals to VCE due to obscure GI bleeding evaluation. The estimated prevalence of small bowel tumors in VCE for obscure bleeding is 6.3% to 12.3%. There is preliminary evidence that VCE

favorably changes the clinical outcome in such cases. Note that when small bowel obstructive symptoms are present the initial work-up should be push enteroscopy or double-balloon enteroscopy rather than VCE.

# **Inherited Polyposis Syndromes**

The lifetime risk of duodenal and small bowel tumors in familial adenomatous polyposis may be as high as 5% to 12%. Other polyposis syndromes, including Peutz-Jeghers syndrome and juvenile polyposis, also portend increased risk for small bowel and duodenal cancers, with a relative risk of 13% for small bowel tumors in Peutz-Jeghers syndrome. This risk has led to a recommended screening

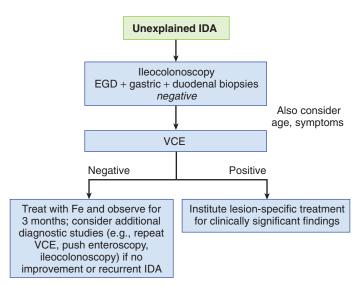

Figure 104-2 The diagnostic algorithm of iron-deficiency anemia (IDA). EGD, esophagogastroduodenoscopy; VCE, video capsule endoscopy.

schedule including EGD or small bowel barium series every 1 to 3 years. VCE has been shown be a sensitive surveillance tool for detecting small bowel polyps in this high-risk population, with a reported sensitivity of over 90%.

# Celiac Disease

Celiac disease has a prevalence of approximately 1% in the general population and is diagnosed by clinical suspicion, serologic and histologic findings obtained by small bowel biopsy ranging from partial to total villous atrophy, and patient response to a gluten-free diet. VCE, which provides a high-resolution magnified view of the small bowel mucosa, can detect mucosal changes such as scalloping, mosaic pattern, loss of normal villous architecture, loss of small bowel folds, and nodularity (Fig. 104-7). These findings by capsule endoscopy have been correlated with the typical histologic findings of celiac disease. Moreover, VCE has been shown to have good sensitivity and excellent specificity in the diagnosis of celiac disease

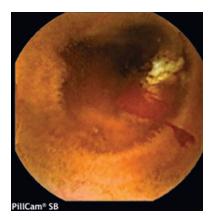

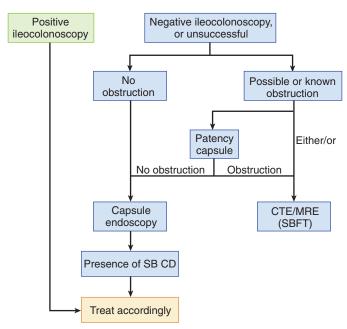

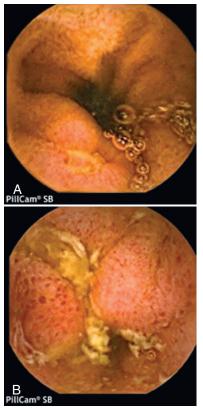

Figure 104-3 Active small bowel bleeding.

#### Suspected SB CD

**Figure 104-4** The role of capsule endoscopy in the diagnosis of Crohn's disease. CTE, computed tomographic enterography; MRE, magnetic resonance enterography; SB CD, small bowel Crohn's disease; SBFT, small bowel follow-through.

**Figure 104-5** Small bowel Crohn's disease. **A,** Aphthous ulcer. **B,** Inflammatory stricture.

Figure 104-6 Small bowel tumor.

even in a "real life" setting and in the detection of more subtle histologic changes. It appears that VCE has a role in the diagnosis of celiac disease when there is a strong clinical suspicion (typical symptoms or positive serology) and EGD with small bowel biopsy is either negative or inconclusive, or the patient does not tolerate or is unwilling to undergo EGD. Furthermore, when patients with diagnosed celiac disease on a strict gluten-free diet develop worrisome symptoms such as weight loss, anemia, fever, bleeding, abdominal pain, or recurrence of malabsorption, or when results of abdominal imaging are abnormal (except for stricture), VCE is indicated to evaluate for small bowel malignancy or enteropathy-associated lymphoma. However, the diagnosis of the typical injury pattern seen with VCE in celiac disease requires considerable expertise, and such patients probably should be referred to specialized centers.

# Monitoring Small Bowel Drug Effects or Side Effects

Several studies have shown that VCE is a sensitive tool to demonstrate small bowel injury caused by nonsteroidal anti-inflammatory drugs (NSAIDs). In fact, VCE can readily detect erythema, erosions, ulcerations, and weblike strictures caused by NSAIDs, even in asymptomatic subjects. There have also been recent reports on VCE being used to monitor response to immunosuppressive therapy to manage intestinal graft-versus-host disease.

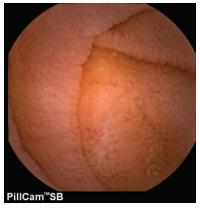

Figure 104-7 Celiac disease: mucosal scalloping.

#### **CONTRAINDICATIONS**

Video capsule endoscopy is contraindicated for use under the following conditions (Box 104-2):

- Patients with known or suspected GI obstruction, strictures, or fistulas based on the clinical picture or preprocedure testing
- Patients with cardiac pacemakers, cardiac defibrillators, or other implanted electromedical devices
- Patients with swallowing disorders

Also, see the pertinent history in the Preprocedure Patient Preparation section.

# EQUIPMENT AND OVERVIEW OF VIDEO CAPSULE ENDOSCOPY SYSTEM

The capsule (Pillcam SB2; Given Imaging, Ltd.) is a disposable device (11 × 26 mm) composed of a light source, lens, metal oxide semiconductor imager, battery, and transmitter (Fig. 104-8). The capsule has a slippery coating that allows easy ingestion and transit with normal intestinal peristalsis. The capsule coating also prevents adhesion of luminal contents and obstruction of the visual field. The battery life is approximately 7 to 8 hours, during which two images per second are acquired and transmitted to a recording device worn by the patient (Fig. 104-9). The images are acquired through the optical dome, creating a visual field of 140 to 176 degrees and a magnification of 8:1. In total, 50,000 to 60,000 images are acquired and transmitted by a sensor array (8 sensors) located on the chest and abdominal wall of the patient to the recording device worn on the patient's belt (see Fig. 104-9). After 7 to 8 hours, the recorder and sensors are removed from the patient and the images are downloaded into a reporting and processing of images and data (RAPID) computer workstation (Fig. 104-10). A continuous video movie is created. Additional features that are currently used include an approximate localization system for each image, a blood detector, an image magnifier, and simultaneous viewing of two to four images.

In summary, the required equipment to perform small bowel VCE includes the following:

- Capsule endoscope
- Computer workstation including a data recorder, batterycharging cradle for the data recorder (Fig. 104-11), a sensor array

# Box 104-2. Relative and Absolute Contraindications to Video Capsule Endoscopy

# Absolute

Clinical or radiographic evidence of bowel obstruction Extensive and active Crohn's disease of the small bowel, with or without strictures

Intestinal pseudo-obstruction Young children (<10 years)

## Relative

Cardiac pacemakers or other implanted electromedical devices

Dysphagia

Extensive intestinal diverticulosis

Pregnancy

Previous abdominal or pelvic surgery

Adapted from Ho KK, Joyce AM: Complications of capsule endoscopy. Gastrointest Endosc Clin N Am 17:169–178, 2007.

**Figure 104-8 A,** PillCam SB2. **B,** A patient holding a capsule. (**A,** Courtesy of Given Imaging, Yoqneam, Israel.)

set with disposable adhesive sleeves for sensor placement on the abdominal wall, and color printer

- A diagram that describes how to locate the sensors on the abdominal wall according to anatomic landmarks
- Drinking water and (disposable) cups for capsule ingestion
- Dark/dimmed light viewing room with a comfortable chair

# PREPROCEDURE PATIENT PREPARATION

Although VCE is a minimally invasive procedure, there are potential procedure-associated risks that need to be explained in detail to the patient before performing the procedure. Emphasis should be put on the *risk of capsule retention* (see later) and the capsule ingestion procedure (mainly to reduce patient anxiety at swallowing a large capsule). For further information, the patient may be referred to several Internet sites (e.g., www.givenimaging.com). The patient should also be provided with a detailed information sheet explaining the VCE procedure (available online at www.expertconsult.com). Immediately before the procedure, explain the alternatives and risks and have the patient sign an informed consent document (available online at www.expertconsult.com).

Any history of dysphagia or neuromuscular disease that may interfere with swallowing the capsule should be carefully sought before

Figure 104-9 Recorder and belt.

Figure 104-10 RAPID computer workstation.

capsule ingestion. History of bowel obstruction or symptoms suggesting partial obstruction such as postprandial cramps, bloating, nausea, or vomiting should be reviewed with the patient. If any positive history exists, a small bowel barium series should be obtained looking for possible strictures or fistulas. Similarly, any history of prior small bowel or other intra-abdominal surgery and any abnormal findings on small bowel imaging suggesting obstruction, stricture, or fistula should be carefully sought and addressed before capsule ingestion.

Before capsule ingestion the patient should adhere to the following regimen:

- Refrain from aspirin or NSAID therapy for a minimum of 14 days before capsule examination. (Even the sporadic use of NSAIDs has been shown to cause erosions and bleeding. Indeed, erosions, aphthous ulcers, and strictures mimicking CD have been reported at VCE in patients who have used NSAIDs. NSAID therapy may not be reported (or even considered) by the patient because many of these medications are sold over the counter or not believed to be significant by patients. Thus, the physician should specifically ask about regular or sporadic NSAID use in the weeks before VCE and recommend that it be discontinued if not mandatory.)
- Refrain from ingesting oral iron therapy, including iron-containing multivitamins, in the 7 days before the VCE procedure.
- Refrain from eating seeds, nuts, or grains the day before VCE. It
  is also advisable to refrain from dairy products and any other
  dark-colored or high-fiber foods. Ample intake of clear fluids the
  day before the procedure is also recommended.
- Fast for 10 hours.
- Consult his or her physician regarding regular medication (e.g., insulin and other diabetes-related medications, antihypertensives) use before VCE examination.

# Use of Prokinetics, Laxative, and Osmotic Bowel Preparations

It has been reported that in as many as 20% of VCE examinations, incomplete small bowel imaging (defined as the capsule not reaching the ileocecal valve/cecum) may occur because of decreased

Figure 104-11 Data recorder and charging cradle.

gastric emptying or prolonged small bowel transit time. Furthermore, turbid or dark intraluminal contents of the small bowel may interfere with the quality of the examination, particularly in the distal ileum. *Prokinetics* are medications given with the aim of accelerating gastric emptying or small bowel transit time, thereby improving the proportion of cases in which the cecum is reached. Bowel preparations are medications given with the primary aim of cleansing the small bowel.

Although current evidence is limited, the International Conference on Capsule Endoscopy in 2006 (ICCE 2006) concluded that small bowel preparation (e.g., polyethylene glycol [PEG], Phospho-Soda, clear liquids) before VCE may not significantly improve small bowel cleanliness and that there is no definitive evidence that such preparations increase the diagnostic yield of small bowel VCE. Therefore, at present, there is no convincing evidence for recommending the routine use of bowel preparations in clinical practice. However, if the use of a bowel preparation is desired by the practitioner, there are several regimens that may be used (Table 104-1). Prokinetic agents (e.g., metoclopramide and erythromycin) may shorten gastric emptying and small bowel transit times, but because they have been less well studied than bowel preparations, no recommendation for their use can be made. Simethicone, an oral antifoaming agent/defrothicant, may be given in its liquid suspension form to improve visualization of the bowel mucosa. Although older age, diabetes mellitus, and inpatient status may be predictive factors for prolonged gastric emptying or small bowel transit time, no firm evidence supports the use of prokinetics or bowel preparation even in these patient subgroups.

# **TECHNIQUE**

It is mandatory to verify that the patient has completed the following steps:

- Fasted for the 10 hours immediately preceding the capsule study
- Maintained a clear liquid diet since lunch the day before the procedure
- Stopped oral iron therapy seven days before the procedure and refrained from aspirin/NSAID use for fourteen days before the procedure
- Signed the informed consent form

The physician should verify, preferably by a checklist or a structured preprocedure visit form, that the indication for VCE is clear and that no contraindications to the procedure exist.

# **Preparing the Equipment**

Because the procedure takes approximately 7 to 8 hours to complete, it is convenient to schedule the patient for VCE examination first thing in the morning. Therefore, disconnecting the sensor array and downloading the data recorder will take place in the middle to late

TABLE 104-1 Bowel Preparation Regimens				
Medication	Dosing			
Sodium phosphate* PEG PEG	90 mL the night before procedure 2 L ingested 16 hr before procedure 4 L:3 L ingested the evening before + 1 L ingested 3 hr immediately before the procedure			

PEG, polyethylene glycol.

\*Sodium phosphate preparations should not be used in patients with renal or cardiac insufficiency/failure and are to be avoided in older patients because of the increased risk of hyperphosphatemia.

Adapted from Villa F, Signorelli C, Rondonotti E, de Franchis R: Preparations and prokinetics. Gastrointest Endosc Clin North Am 16:211–220, 2006.

afternoon. The following items should be readily available at the time of patient presentation:

- A fully charged data recorder (as indicated by the battery indicator light), after patient check-in procedure has been launched using the RAPID workstation
- PillCam SB in its original sealed package
- One disposable cup of water, a sensor array with adhesive sleeves, a sensor location diagram for correct sensor placement on abdomen, and a belt for the data recorder

# **Getting Started**

The patient should lie supine and the sensor array should be placed on the abdomen at the locations indicated by the sensor location diagram. Care should be taken to be sure that the sensors are firmly attached in the correct location. The patient should then stand, wearing his or her clothes, and make sure that no discomfort is caused by the sensors. The belt, with the data recorder in place, is worn over the patient's clothing (see Fig. 104-9). The capsule should then be removed from its packaging. Once the capsule is detached from its cell (and magnet) it is important to verify that the eight light-emitting diodes (LEDs) start to work (lights on the capsule will begin to flash immediately on detachment) and that the capsule transmission indicator on the data recorder starts flashing blue. This indicates that the data recorder is acquiring the signal from the capsule. The patient then takes the capsule (see Fig. 104-8), taking great care not to drop it, and places it in his or her mouth (the orientation of the capsule in the mouth is not important). The patient is then instructed to swallow the capsule while drinking a full glass of water. In cases when swallowing is unsuccessful, a repeat attempt should be made. If further attempts are unsuccessful, the capsule should be put back into its cell and magnet so that battery life is preserved.

Endoscopic placement of the capsule into the stomach or duodenum is possible using a video endoscope and a dedicated capsuleholding suction cup, snare, or endoscopic net. However, this procedure should be performed only by an experienced endoscopist, and as soon as possible, because the battery may not completely stop and capsule battery life span may be shortened.

After capsule ingestion the patient should be instructed as follows:

- Remain in the clinic area for approximately 15 to 30 minutes to make sure that no technical problems occur.
- Pay attention that the flashing blue LED on the data recorder is on.
- Treat the data recorder with the utmost care.
- Refrain from being near areas of magnetic fields such as magnetic resonance imaging (MRI) machines, security gates, and the like. Certain industrial magnetic fields may interfere with transmission of the images.
- Refrain from liquid intake for 2 hours and food intake for 4 hours after capsule ingestion.
- Contact the medical staff in case of severe abdominal pain, nausea, or vomiting.
- Note capsule excretion. In case of any doubt, any symptoms of bowel obstruction, or before MRI, an abdominal radiograph should be performed to verify capsule excretion. For patients who do not visualize/observe capsule excretion and in whom the colon is not visualized on the video imaging, an abdominal radiograph should be performed on day 14 to identify those with capsule retention.

Figure 104-12 RAPID viewing screen.

# Video Reviewing

#### **General Information**

- The average reviewing time for small bowel VCE is usually 30 to 60 minutes.
- Video reviewing should take place in a semidarkened room and, because video reviewing requires considerable concentration, no visual distractions should be allowed. However, listening to music is possible.
- Before attempting to review VCE videos it is imperative to be familiar with the software and to have experience in interpretation of VCE findings. We strongly encourage attending Capsule Endoscopy courses such as those provided by the American Society for Gastrointestinal Endoscopy (www.asge.org). Furthermore, the authors strongly recommend reviewing your initial 10 to 20 capsule videos with proctoring from a colleague experienced in VCE.

# Video Reviewing Procedure

- We recommend using the simultaneous two-picture viewing mode (Fig. 104-12), setting the video speed to 18 to 22 in the manual mode (M-mode, preferable) or lower speed using the automated mode (A-mode).
- It is of utmost importance to determine and mark the following anatomic landmarks:
  - First image of the gastric folds
  - First duodenal image (identified by the first image where villi on the mucosa are seen [Fig. 104-13]; usually passage of the capsule through the pylorus is seen immediately before this point of transit)

Figure 104-13 Small bowel: normal villi.

- First cecal image (the first image where villi are absent, fecal matter is dominant, and typically where there is a lack of the characteristic peristalsis of the small bowel)
- Capsule findings should be reported by creating a thumbnail from the image. Preferably, each pathologic finding should be defined and noted in the thumbnail's comment. In cases where the nature of the finding is unclear, refer to the image atlas in the product software or an endoscopic atlas or VCE atlas (e.g., Keuchel and colleagues, 2006).
- Capsule transit time through the stomach and small bowel is another aspect of video interpretation. Transit delays may suggest stricture or obstruction, and should be noted. If the capsule fails to reach the ileocecal valve or did not traverse the ileocecal valve into the cecum during the time of recorded video, this should be noted in the report. Careful follow-up of these patients is warranted to verify capsule excretion in the following days and that no symptoms or signs of small bowel obstruction appear. A capsule present for more than 14 days after the capsule examination is considered to be retained.
- Use of the suspected blood identification system: The RAPID software provides an accessory tool for detecting blood in the small bowel. This software tool has limited sensitivity and specificity. The blood detector does not replace careful reviewing of the entire video for bleeding and bleeding sources.
- Localization of findings: Each clinically significant finding detected during video reviewing should be considered for further management (e.g., referral for surgery, enteroscopy, or ileocolonoscopy). This is usually done by referring to the anatomic landmarks. Although the software system provides an estimated location for each image by using the localization system, exact localization of findings in the small bowel is difficult. It is useful to use terms such as duodenum, proximal jejunum, distal jejunum/proximal ileum, distal ileum, and terminal ileum when describing the location of a finding. This description is completed using noted anatomic landmarks, transit times, and the timing of each thumbnail, but because of the variable speed of the capsule's peristaltic movement through the intestine, this method is not very accurate.
- Creating the report
  - Verify that the patient demographic details and reason(s) for capsule endoscopy referral are reported and inserted into the appropriate report fields during patient check-in. If not, you may do this when creating the VCE report.
  - A brief summary of the VCE findings (e.g., gastric and small bowel) should be typed in the box specified for procedure information and findings.
  - The final diagnosis and recommendations for further work-up or treatment should be stated and typed in the appropriate field.

# **COMPLICATIONS**

# **Clinical Complications**

Clinical complications include complications of capsule ingestion, capsule retention, and incomplete examination. Capsule retention (defined as presence of capsule 14 days after capsule ingestion) is by far the most serious of these. An incomplete examination may be considered a technical problem rather than a clinical complication, and therefore is not discussed here. The safety of VCE has not been examined systematically in pregnant women and in children younger than 10 years of age. Therefore, we do not recommend the use of VCE in the primary care setting in these patients.

#### Capsule Retention

At the 2005 ICCE, capsule retention was defined as an endoscopic capsule remaining in the digestive tract for more than 14 days. Capsule retention has been further defined as failure of the capsule to be excreted unless surgical, endoscopic, or medical interventions are performed. The prediction of this serious complication is difficult in that no single modality, including small bowel follow-through, may accurately predict it. However, experts believe that obtaining a careful history is perhaps the best single method to identify high-risk patients. Important clues to possible small bowel stricture/stenosis include the following:

- Chronic NSAID use
- Suspected or known CD
- History of intestinal surgery
- Suspected small bowel tumor
- History of abdominal radiation therapy
- Suspected mesenteric ischemia

Symptoms such as pain, nausea or vomiting, and abdominal distention may also indicate increased potential for capsule retention. The overall incidence of capsule retention is 1% to 2%, with two thirds of capsule retentions occurring in CD-related strictures. The relative incidence rates of capsule retention are shown in Table 104-2.

#### PREVENTION OF CAPSULE RETENTION

- Careful history taking and risk stratification according to the aforementioned groups.
- Small bowel follow-through: This is currently the best way to establish the presence of small bowel strictures. Possible disadvantages include false-negative results and radiation exposure.
- Patency capsule (Agile Patency System; Given Imaging, Ltd.): Made of lactulose, this capsule is specifically designed to dissolve spontaneously after 40 hours in the bowel. The capsule has a radiopaque tag, a timer, and a radiofrequency identification tag. It is readily detected by plain abdominal radiographs and by the detection device of the Agile System, thus enabling localization of the stricture causing the obstruction. The patency capsule disintegrates completely after 80 to 100 hours. Current experience with the patency capsule is that it is no more sensitive than small bowel follow-through or computed tomographic enteroclysis in detecting small bowel strictures. Moreover, 2 of 22 (11%) patients who swallowed the patency capsule developed small bowel obstruction that required surgery. Thus, given the comparable sensitivity and the risk for capsule-associated bowel obstruction, we do not recommend the use of the patency capsule in the work-up of a suspected small bowel stricture.

**TABLE 104-2** Capsule Retention Rates According to Video Capsule Endoscopy Indication

Indication	Retention Rate
Healthy volunteers All comers Suspected Crohn's disease Obscure gastrointestinal bleeding Known Crohn's disease Suspected bowel obstruction	0% 0.75% 1.4% Up to 5% Up to 8% 21%

Modified from Eliakim AR: Video capsule endoscopy of the small bowel (PillCam SB). Curr Opin Gastroenterol 22:124–127, 2006.

#### MANAGEMENT OF CAPSULE RETENTION

- Immediate referral to plain abdominal radiographs and possible surgery in cases of clinical symptoms and signs of small bowel obstruction.
- Extraction of the retained capsule by means of push enteroscopy, double-balloon enteroscopy, or surgery. Because most patients with capsule retention are asymptomatic, the extraction is not urgent. Thus, referral for further evaluation by a gastroenterologist or a surgeon is warranted promptly but not urgently.
- A prokinetic agent such as metoclopramide or erythromycin may also be prescribed to accelerate the small bowel transit time and induce capsule passage.

#### **Swallowing Disorders**

Inability to swallow the capsule or (rarely) aspiration of the device has been reported in up to 1.5% of VCE procedures. Difficulty in swallowing may be overcome by introduction of the capsule by means of an oroesophageal overtube or EGD with a snare with a basket or foreign object retrieval device. Thus, patients who are unsuccessful in swallowing the capsule may be referred to a center dedicated to VCE. Aspiration of the capsule can usually be overcome simply by coughing. In cases of suspected aspiration, referral for a chest radiograph or bronchoscopy is indicated.

# **Technical Complications**

In the largest series to date, Rondonotti and colleagues (2005) reported an overall 9% technical failure rate in 733 patients. These technical failures included gaps in image recording; shortened battery operation; malfunction of the battery package; and failure of capsule activation, image downloading, and the localization system. In 33% of cases with technical problems, the diagnosis was hampered. Overall, a total of 3% of all hampered diagnoses were attributed to technical problems. Interference with communication between the capsule and recorder is also a technical problem. This interference may be caused by nearby electromagnetic devices such as cardiac pacemakers, electronic article surveillance systems, and cellular telephones. Because radiofrequency electrosurgery and cellular telephones have been reported to interfere with cardiac pacemaker functioning, the presence of an implantable cardiac device is considered a relative contraindication to VCE. However, a small series of patients with pacemakers who underwent VCE have been reported to have no arrhythmias or pacemaker malfunction on Holter electrocardiographic monitoring during VCE. Similarly, the pacemakers did not interfere with VCE in these patients. Leighton and colleagues (2005) have reported similar results in a small series of five patients with an implantable cardiac defibrillator.

# CURRENT AND FUTURE DEVELOPMENTS IN VIDEO CAPSULE ENDOSCOPY

Since the FDA approval of the first M2A capsule in 2001, many new developments have been put into clinical use. New capsules, such as PillCam ESO with double-sided cameras and acquisition of 14 frames per second for the detection of esophageal diseases, including Barrett's esophagus and esophageal varices, and PillCam SB2 with better illumination technology and a wider visual field of 156 degrees for improved accuracy in the diagnosis of small bowel diseases, have recently been approved by the FDA for clinical use. Moreover, a new capsule, PillCam Colon, for the diagnosis of colonic mucosal disease is currently under investigation and has been approved (given a CE mark) for use in the European Union. Improvements in the diagnostic software allow for simplified viewing modes and shorter video review time, making this procedure even easier to use and more widely accepted. It is therefore imperative for any physician involved in VCE to be familiar with current and future developments in this rapidly evolving technology.

# Inguinal Hernia Reduction

George G. Zainea

The *indirect inguinal hernia* is the most common type of groin hernia. It occurs lateral to the inferior epigastric vessels. The hernia sac passes through the internal inguinal ring. It is associated with patency of the processus vaginalis. This hernia is typically seen in children and young adults (Figs. 105-1 and 105-2).

The direct inguinal hemia occurs medial to the inferior epigastric vessels. It protrudes through the posterior inguinal floor. It is more commonly seen in adults (see Figs. 105-1 and 105-2). The risk of incarceration is less than that of indirect inguinal hernia.

Femoral hernias, usually found in adult women, are seen far less commonly. The protrusion occurs beneath the inguinal ligament just medial to the femoral vessels in the upper thigh. The risk of incarceration and strangulation is high with this type of hernia (see Figs. 105-1 and 105-2).

#### **DIAGNOSIS**

Diagnosis involves palpation with the patient both supine and standing. An incarcerated groin hernia manifests as a nonreducible, painful groin bulge. Associated intestinal obstruction may also be present.

A Valsalva maneuver (grunting or coughing) allows the appreciation of a palpable impulse in a true hernia. Auscultation may reveal bowel sounds. Transillumination can be performed to assist with diagnosis.

## **DIFFERENTIAL DIAGNOSIS**

The history and physical examination usually allow the physician to exclude other disorders that may mimic an incarcerated groin

Incisional hernia
Umbilical hernia
Direct inguinal hernia
Femoral hernia
Indirect inguinal hernia

Figure 105-1 Hernia locations in the abdominal wall. (Modified from Abel ME, Glassman SL, Harris RJ, Gibson TJ: The Hernia Surgery Book: How Hernias Develop and How They're Repaired. San Bruno, Calif, StayWell, 1999.)

hernia, such as an *inflamed lymph node*, which is usually evident by history and on palpation; a *dilated varicose vein*, which may appear as a bulge in the inguinal region; a large lipoma; and a *hydrocele* of the spermatic cord, which typically is not tender, does transilluminate, and rarely is associated with an acute presentation. Other disorders to consider include *testicular torsion*, which manifests as extreme scrotal pain and swelling. With torsion, pain may be intensified with scrotal elevation, and swelling is usually confined to beneath the pubic tubercle. Finally, an *undescended testicle* may appear as an isolated groin bulge. This should be suspected if the gonad is not present in the scrotal sac.

# **TECHNIQUE**

By definition, a hernia that is nonreducible is *incarcerated*. Incarceration usually involves either the bowel or the omentum. The practitioner may see intestinal obstruction with bowel incarceration; however, the most feared complication of incarceration is strangulation. With strangulation, the blood supply to the intestine is compromised, and ischemic necrosis and gangrene may result.

The decision to reduce incarcerated hernias requires clinical judgment. If strangulation is suspected, the situation is best dealt with immediately in the operating room. Patients with strangulation typically appear ill, and may be febrile. The bulge is extremely tender, and overlying skin erythema may be present.

If strangulation is not suspected, the clinician may attempt closed reduction as follows:

- 1. Place the patient in the supine Trendelenburg position. This allows gravity to assist with hernia reduction.
- 2. Administer a narcotic for analgesia and intravenous diazepam for muscle relaxation. After sedation, allow for passive reduction of the hernia over a 30- to 40-minute period.
- 3. If the attempt at passive reduction is unsuccessful, proceed with an attempt at active reduction. Place one hand over the neck of

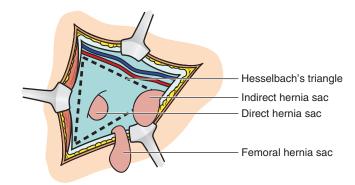

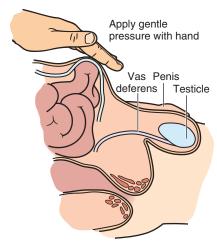

Figure 105-2 Operative view of inguinal and femoral hernias.

the hernia sac to guide its contents into the peritoneal cavity. Use the other hand to provide gentle and steady distal-to-proximal compression over the hernia (Fig. 105-3).

**Figure 105-3** Application of gentle pressure to reduce inguinal hernia. (Modified from Abel ME, Glassman SL, Harris RJ, Gibson TJ: The Hernia Surgery Book: How Hernias Develop and How They're Repaired. San Bruno, Calif, StayWell, 1999.)

Using these techniques, the clinician should be able to reduce one third to one half of incarcerated groin hernias. Patients with irreducible groin hernias or incarcerated femoral hernias (which are seldom reducible) should be referred to a surgeon immediately.

Infants and children who successfully undergo closed reduction of inguinal hernias should be admitted to the hospital for surgical repair. An adult patient with suspected compromised bowel in the reduced hernia should be admitted to the hospital for observation. Adults who undergo successful closed reduction and return home should soon thereafter undergo elective hernia repair. A truss should be used only temporarily to prevent recurrent protrusion before surgery can be performed.

# OFFICE TREATMENT OF HEMORRHOIDS

George G. Zainea • John L. Pfenninger

Hemorrhoidal disease occurs in approximately 50% to 80% of the U.S. population. Although this disease is rarely fatal, it accounts for a great deal of human pain and suffering. Internal hemorrhoids are the most common cause of lower gastrointestinal (GI) bleeding. Nonetheless, it is imperative that the clinician confirm that bleeding is indeed originating from hemorrhoidal disease and not from a more proximal lesion. Occasionally, bleeding can be severe and is associated with anemia.

Most hemorrhoidal symptoms can be managed with medical therapies that include suppositories, topical agents, and fiber supplementation. Patients who fail medical therapies are appropriate candidates for in-office treatments of hemorrhoids. Only a minority of individuals requires definitive treatment for severe symptomatic hemorrhoids with a surgical hemorrhoidectomy or hemorrhoidopexy. A hemorrhoidectomy requires general or regional anesthesia and is associated with significant discomfort and loss of time from work and usual activities after surgery.

Rubber-band ligation is a time-tested and proven method for treating *internal hemorrhoids*. However, other approaches have been developed, with infrared photocoagulation (IRC) being used most frequently and, rarely, sclerotherapy. Direct-current (Ultroid) and radiofrequency (Bicap) techniques were described in the first edition of this text. Bicap is no longer available, and although Ultroid has recently been reintroduced to the market, the time required and the cost of the probes make it less likely to be used. Cryotherapy was also used in the past but not currently because of the availability of more cost-effective modalities. These therapies can be used selectively or in combination depending on the extent and severity of internal disease. Lasers have also been used for the treatment of internal disease. The treatment for *external hemorrhoid disease* has been unchanged for decades.

Two meta-analyses have been reported on the treatment of internal hemorrhoids. One concludes that band ligation is best, whereas the other supports IRC. In both instances, hemorrhoid symptoms resolved in 80% to 90% of properly selected cases.

The physician must know the anorectal anatomy (see Chapter 97, Clinical Anorectal Anatomy and Digital Examination) and must be able to perform a thorough anoscopic examination (see Chapter 98, Anoscopy) to appropriately assess and treat hemorrhoids.

After completion of any of these procedures, a medical program to regulate bowel habits should be implemented to prevent recurrence, which is as important as the surgical intervention itself.

#### **CLASSIFICATIONS AND SYMPTOMS**

Hemorrhoids are enlarged arteriovenous vessels within fibrous tissue and are classified according to their origin either above or below the dentate (pectinate) line. Those developing from *above the* 

dentate line are internal hemorrhoids; those from below are external hemorrhoids. It should be clear that classification depends on *origin*, not on the location of the most distal portion of the hemorrhoid (Fig. 106-1).

Hemorrhoids above the dentate line—internal hemorrhoids—are covered by mucosa and do not have somatic sensory innervation. Thus, internal hemorrhoids are well suited for treatment in the office setting without anesthesia because they lack pain fibers. Those below the dentate line—external hemorrhoids—are covered by skin (anoderm) and are extremely sensitive. Treatment of external hemorrhoids requires some form of anesthesia. Mixed hemorrhoids refers to those vessels that originate right at the dentate line or to the presence of both internal and external hemorrhoidal tissue in continuity.

The anal canal can be divided into eight segments. With the patient lying in the left lateral decubitus position, they are as noted in Figure 106-2A. Internal hemorrhoids usually occur in three major positions based on the vascular architecture of the anal canal: the right anterior, right posterior, and left lateral positions (Fig. 106-2B). However, they can occur anywhere and even be circumferential. They also seem to "shift" with insertion of the anoscope, so absolute position is not that critical.

Internal hemorrhoids are also characterized by their size and degree of prolapse from grades I to IV, as noted in Table 106-1 and Figure 106-3. Symptoms of internal hemorrhoids include *painless* bleeding, prolapse, aching after defecation, and discharge. The key step in diagnosis and classification of internal hemorrhoids is anoscopic examination (see Chapter 98, Anoscopy). External hemorrhoids can form clots that are *painful*. Patients then present with a "painful lump."

Hemorrhoidal skin tags are residual fibrotic masses of stretched skin. Their size can vary significantly. They are generally asymptomatic except for occasional pruritus. Most commonly, when larger, they can cause problems with hygiene.

Approximately 25% of internal hemorrhoid symptoms do not respond adequately to medical treatment and require further therapy. Most thrombosed external hemorrhoids require evacuation or excision to provide symptomatic relief.

#### **INTERNAL HEMORRHOIDS**

#### **Indications**

Bleeding or other symptomatology, such as prolapse, from internal hemorrhoids that has failed medical management (i.e., bulk agents, suppositories, topical preparations, and sitz baths) is an indication for treatment.

**NOTE:** The mere presence of hemorrhoids alone, without symptoms, is not necessarily an indication for treatment.

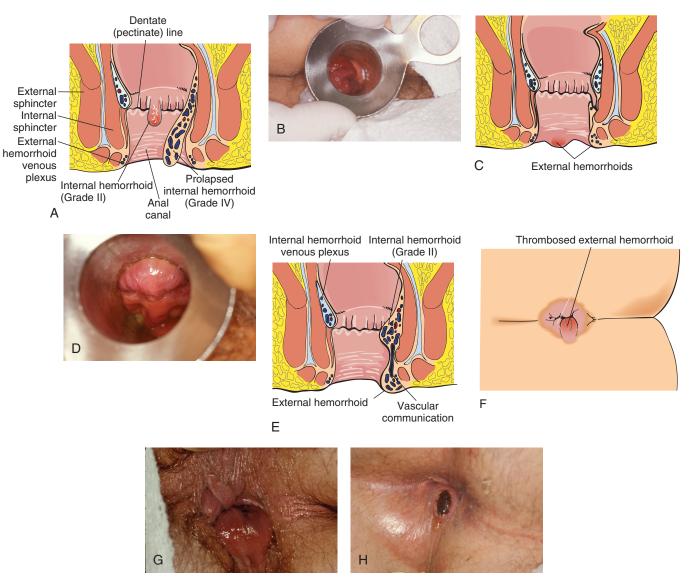

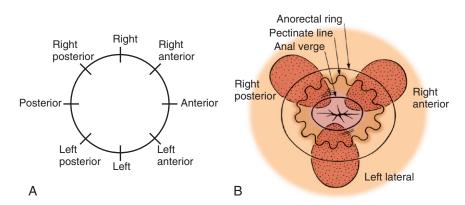

Figure 106-1 Various types of hemorrhoids. **A,** Internal hemorrhoid. Note that although an internal hemorrhoid may be visible "externally" (grade IV), it is classified by its origin, which, as shown here, is above the dentate line. **B,** Internal hemorrhoid as seen through the Ives slotted anoscope. **C,** External hemorrhoids. **D,** External hemorrhoid as seen through the Ives anoscope. **E,** Mixed hemorrhoid disease (both internal and external hemorrhoids with a vascular communication). **F,** Thrombosed external hemorrhoid. **G,** Large acute thrombosed hemorrhoid. **H,** Normal progression of a thrombosed external hemorrhoid 4 to 5 days after occurrence. The skin over the top becomes necrotic and appears to be a thin membrane. (**A, C, E,** and **F,** Redrawn from Pfenninger JL, Surrell J: Nonsurgical treatment options for internal hemorrhoids. Am Fam Physician 52:821–837, 1995. Original art copyrighted by Steve Oh. **B, D, G,** and **H,** Courtesy of John L. Pfenninger, MD, The Medical Procedures Center, PC, Midland, Mich.)

**Figure 106-2 A,** Representation of eight segments in the rectum as seen through a slotted (Ives) anoscope, with the patient in the left lateral decubitus position. **B,** Usual three primary hemorrhoidal groups.

TABLE 106-1 Classification of Internal Hemorrhoids			
Grade	Description		
         V	Small, do not prolapse Medium, prolapse and return spontaneously Large, prolapse but reduce manually Largest, prolapse, not reducible		

#### **Contraindications**

- Bleeding diathesis (relative). If on warfarin, the international normalized ratio (INR) should be in the therapeutic range. There is always an increased risk of bleeding if the patient is on aspirin or clopidogrel, but generally this is not a contraindication to treatment.
- Pregnancy or immediately postpartum (<8 weeks).
- Inflammatory bowel disease.
- Anorectal fissures.
- Active anorectal infections.
- Acquired immunodeficiency syndrome or other immunodeficiency states.
- Portal hypertension (relative).
- Rectal wall mucosal prolapse.
- Anorectal tumors.

Recommendations for antibiotic subacute bacterial endocarditis prophylaxis have been updated (see Chapter 221, Antibiotic Prophylaxis). Basically, antibiotics are *not* indicated for hemorrhoidal procedures. For those in the very–high-risk categories, they would be optional.

# **Preprocedure Patient Preparation**

 Give the patient one or two enemas before the procedure. Although not absolutely necessary, it is aesthetically helpful and improves visualization of the anatomy.

- Ask the patient to avoid aspirin or clopidogrel for 1 week before treatment in low-risk situations.
- Provide a patient education handout to ensure informed consent (see the sample patient education handouts online at www. expertconsult.com).
- 4. A complete history of the complaints as well as the pertinent past medical history and physical examination are essential. Record these on the sample encounter forms (go to www.expertconsult.com) that summarize the information.
- 5. The patient may be examined and treated in the left lateral decubitus position, which is usually more comfortable, the prone jackknife position, or even in the customary stirrups. The latter two positions can be used when exposure is difficult. No sedation is necessary for a patient having only anoscopy and internal hemorrhoid treatment. The patient may take four ibuprofen 200-mg tablets 1 to 2 hours before the office visit. Before performing anoscopy, perform an external visual and a digital anorectal examination. Ask the patient to perform a Valsalva maneuver (bearing down) to rule out full-thickness rectal prolapse. (Occasionally, examination with the patient sitting on the commode is necessary to assess for this.)

**NOTE:** Only internal hemorrhoids are treated by IRC, banding, or sclerotherapy. Treatment of external hemorrhoids requires excision and is associated with pain, so at least local anesthetics are needed.

#### **Treatment**

Rubber-band ligation (Barron or McGivney ligation), IRC, and sclerotherapy for internal hemorrhoids are discussed in the following sections. A summary of techniques and their indications is found in Table 106-2. The treatment of external hemorrhoids is covered later in this chapter and the treatment of perianal skin tags is dealt with separately in Chapter 108, Removal of Perianal Skin Tags (External Hemorrhoidal Skin Tags). Because of the associated discharge and poor patient acceptance, cryotherapy is not covered in this discussion.

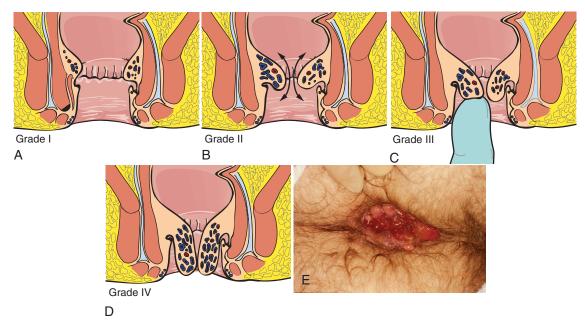

Figure 106-3 Grading of *internal* hemorrhoids. **A,** Grade I hemorrhoids are present and identifiable. **B,** Grade II hemorrhoids prolapse with a bowel movement but return spontaneously. **C,** Grade III hemorrhoids prolapse and can be replaced manually. **D,** Grade IV hemorrhoids remain prolapsed in spite of all efforts at reduction and are often associated with varying amounts of mucosal prolapse. **E,** Grade IV prolapsed internal hemorrhoid. (**A–D,** From Pfenninger JL, Surrell J: Nonsurgical treatment options for internal hemorrhoids. Am Fam Physician 52:821–837, 1995. Original art copyrighted by Steve Oh.)

## **Rubber-Band Ligation**

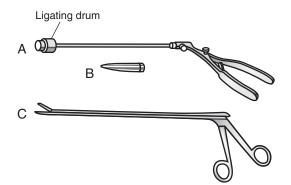

Rubber-band ligation involves placing a rubber band around the base of an internal hemorrhoid. The ensnared tissue undergoes necrosis and sloughs. Rubber-band ligation is used for treatment of second- or third-degree bleeding or prolapsing internal hemorrhoids.

# **EQUIPMENT**

- Slotted Ives anoscope (see Chapter 98, Anoscopy, Fig. 98-1)
- McGivney ligator with bands (or an acceptable alternative device; Fig. 106-4) is the traditional applicator. Alternatively, a disposable hemorrhoid ligator is available, the O'Regan Hemorrhoid Banding System (Fig. 106-5).
- Alligator forceps (similar to long-handled Allis clamp)
- External light source
- Large obstetric/gynecologic cotton swabs

#### **TECHNIQUE.** See Figure 106-6.

- Load the ligating drum with two bands. Insert the cone into the drum and slide the bands over it. A small amount of liquid soap on the cone will facilitate this. Hold the handle with the other hand to prevent the inadvertent sliding of the outer drum over the inner drum of the ligator while loading.
- Insert the anoscope and visualize the hemorrhoid to be ligated. Treat the largest hemorrhoid group, or the obviously bleeding source, first. Have an assistant stabilize the anoscope.
- 3. With one hand, draw the hemorrhoidal tissue into the ligating drum with an alligator forceps. If the patient experiences pain, grasp the hemorrhoidal tissue more proximally. Pull only hemorrhoidal tissue into the ligator; avoid excessive mucosa.
- 4. With the other hand, grasp the handle of the ligator and push forward slightly. Squeeze the handle. The outer drum slides over the inner drum, displacing the rubber bands around the hemorrhoid.
- Reposition or withdraw the anoscope. Patient tolerance is highest if only one hemorrhoid group is treated per visit. However, some physicians treat more than one segment per visit. Avoid circum-

**Figure 106-4** McGivney ligator. **A,** Ligator. **B,** Cone to load bands. **C,** Forceps to grasp hemorrhoid.

ferential ligation because it may increase pain, and the tension on the mucosa may lead to nonhealing fissures.

Common

OR

#### COMPLICATIONS

- Spotting can be expected for 8 to 10 days. Profuse bleeding, although rare, occurs 1 to 2 weeks after the procedure, when the hemorrhoidal tissue sloughs. Bleeding can be significant and occasionally requires active intervention.
- Patients may experience a dull ache for 2 days after the procedure.
   If severe pain is experienced during the procedure, the band will need to be removed with scissors. It was applied too far distally.
- Thrombosis of external hemorrhoids occurs rarely and is treated symptomatically or with excision.
- Sepsis with pelvic cellulitis (perineal sepsis) is a serious complication, but it rarely occurs. Patients complain of fever, increasing perineal pain, swelling, inability to urinate, or dysuria. Treatment requires hospitalization, broad-spectrum antibiotic administration, and débridement.
- Slow healing or nonhealing of the treatment site can lead to formation of an anal fissure.

# **ADVANTAGES**

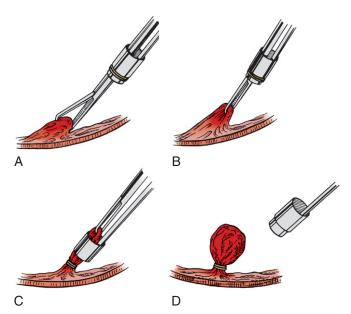

- The instrument itself is inexpensive, and there are no disposable tips to replace.
- Higher grades of hemorrhoids can be treated.
- The procedure is quick.
- The procedure is easy to learn.

## DISADVANTAGES

The procedure is somewhat more uncomfortable than other techniques, and significant complications have been reported (e.g., perineal sepsis).

**Figure 106-5** O'Regan disposable banding unit. **A,** Trocar for insertion of anoscope. **B,** Anoscope. **C,** Loading cone for bands. **D,** Syringe for suction to pull up hemorrhoid. **E,** Sleeve that fits over syringe apparatus that pushes bands off onto hemorrhoids. **F,** Penlight inserted into anoscope handle for light.

**Figure 106-6** Rubber-band ligation. The hemorrhoid is gently grasped (**A**) and brought into the drum of the ligator (**B**). Two rubber bands are released (**C**). Appearance of the ligated hemorrhoid after equipment is removed (**D**). If the patient tolerates the grasping of the hemorrhoid with forceps, ligation can be performed with minimal or no discomfort.

 Two people are needed to perform the procedure (the operator and the assistant, who holds the anoscope).

**POSTPROCEDURE PATIENT EDUCATION.** See the patient education handouts online at www.expertconsult.com.

- Inform the patient that mild aching discomfort may be experienced over the next 2 days.
- Ask the patient to report any excessive bleeding, fever, dysuria, inability to urinate (a sign of perineal sepsis), or increasing pain.
- Ask the patient to follow up in 4 to 6 weeks for reexamination and further banding, as needed.

#### Infrared Coagulation

#### **EOUIPMENT**

- Infrared coagulator (Redfield Corporation, Rochelle Park, NJ; Fig. 106-7)
- Slotted Ives anoscope (Redfield Corporation; see Chapter 98, Anoscopy, Fig. 98-1)
- External light source
- Large obstetric/gynecologic cotton swabs

**NOTE:** IRC units are not submersible for cleaning. Instead, they use a disposable sheath that is changed for each visit (see Fig. 106-7B). It is imperative not to immerse the newer units (in contrast to the older units) in sterilizing solutions.

**TECHNIQUE.** Infrared light is applied to the *base* of the internal hemorrhoid, forming a white coagulum that ulcerates and then forms a scar. The diameter of burn correlates with the size of the probe tip, which is usually 6 mm. The depth of penetration correlates with the time of the pulse, which is generally 1.5 to 2 seconds. Infrared coagulation is used for first- and second-degree and smaller third-degree internal hemorrhoids. It can be used for larger hemorrhoids (use a 2- to 2.5-second setting), but treatment may need to be repeated in 4 to 6 weeks. It is a painless procedure, and although more than one hemorrhoid group is sometimes treated, most clinicians begin by treating only one complex to determine patient tolerance. Treatment of more than one complex of hemorrhoids at a time may increase post-treatment discomfort and the other complications, especially bleeding. A teaching video describing this technique is available from Redfield Corporation.

- 1. With the patient in the left lateral decubitus position, insert the Ives slotted anoscope and identify the hemorrhoid to be treated. Insert the 6-mm IRC probe.
- Press the probe tip onto the hemorrhoid itself, or preferably on the most proximal portion of the hemorrhoid. Only light pressure is needed.
- 3. Pull the trigger and keep it compressed. The unit has an incorporated time switch that limits exposure and will turn off automatically. The typical setting is 1.5 seconds. Generally, four to six separate applications are made for each hemorrhoid group.

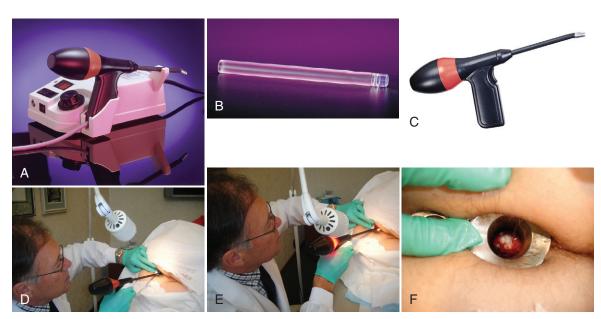

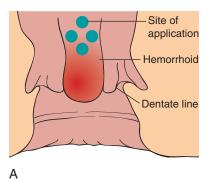

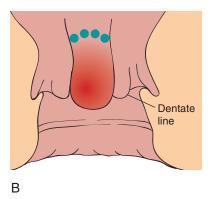

Figure 106-7 Infrared coagulator (IRC) unit (A), sheath (B), and handpiece (C). The tip of the IRC is inserted through the Ives slotted anoscope and placed on the base of the hemorrhoid (D). When the unit is activated (E), a light is visible (noted here in the bulb of the handpiece) that automatically shuts off after the programmed time, usually 1.5 to 2 seconds. The internal hemorrhoid appears white over the treated area (F). (A–C, Courtesy of Redfield Corporation, Rochelle Park, NJ; D–F, Courtesy of John L. Pfenninger, MD, The Medical Procedures Center, PC, Midland, Mich.)

**Figure 106-8** Treatment of base (proximal portion) of the internal hemorrhoids using infrared coagulation. **A,** Diamond shape. **B,** Linear method. Each circle indicates a single application for 1.5 to 2 seconds. Up to six applications per visit may be needed per hemorrhoid segment.

One group is treated per visit at 4- to 6-week intervals. For the first treatment, select the hemorrhoid that is bleeding or that is the largest. Larger hemorrhoids and grade III hemorrhoids may require more than one treatment session or a longer exposure (2 seconds).

**CAUTION:** Do not overlap treatment sites. Overlapping increases the depth of burn. Place the probe adjacent to a previous site in a linear fashion or in a diamond shape, but do not overlap if possible (Fig. 106-8). If overlapping does occur, it rarely causes a significant problem, but purposely avoid it *if possible*.

- 4. Wipe off the tip with saline-soaked gauze between applications. This allows the tip to cool and cleans the end. If a loud "pop" is heard, there is debris or mucus between the tip and the mucosa. No damage is done, but the sudden noise can be frightening to the patient (and the clinician). It will sound much like a small firecracker.
- Realign the anoscope and apply treatment to another hemorrhoidal group if more than one group is to be treated.
- 6. Remove the anoscope. No special aftercare is needed.

#### COMPLICATIONS

- Patients may experience a mild, dull, aching pain lasting up to 2 days after treatment.
- Minor bleeding may be encountered for up to 2 weeks after the procedure. More bleeding can be expected at 10 to 14 days when the eschar sloughs. This can usually be managed conservatively but very rarely will require topical astringents or maybe even a suture.
- Rarely, patients experience a thrombosed external hemorrhoid in the area after treatment.
- Rarely, slow-healing ulcers can be encountered.
- Slow healing or nonhealing of the treatment site can lead to formation of an anal fissure.

#### **ADVANTAGES**

- It is an essentially painless procedure.
- There have been no reported cases of perineal sepsis.
- The procedure is quick, simple to learn, and cost effective.
- The procedure is well tolerated by patients.
- There are no costs for disposable probes, but disposable vinyl sheaths are used.
- It can be used in patients with pacemakers.
- The unit can also be used to remove tattoos, reduce nasal turbinates, stop bleeding from biopsy and hair donor sites, and treat verrucae and condylomata.
- The unit is well made and requires little maintenance.

#### **DISADVANTAGES**

- The procedure is not very effective for advanced third-degree hemorrhoidal disease and works poorly for fourth-degree hemorrhoidal disease.
- The unit costs more than the materials for band ligation.

**POSTPROCEDURE PATIENT EDUCATION.** See the patient education handouts online at www.expertconsult.com.

- Ask the patient to follow up in 4 to 6 weeks to treat residual disease or another group of hemorrhoids. In the elderly or compromised patient (e.g., diabetes), it is best to wait longer.
- Ask the patient to report any severe symptoms of pain, fever, or inability to urinate.

#### Sclerotherapy

Sclerotherapy is used for treatment of first- or second-degree internal bleeding hemorrhoids. Injection of 1 to 2 mL of sclerosant into the internal hemorrhoid causes sclerosis and fixation of the submucosa to the underlying muscularis. This technique is relatively quick. All three major hemorrhoidal groups can be treated at one sitting. It is a useful technique for a patient on warfarin. Unfortunately, it has not been as effective as other modalities and has been associated with impotence, the reason for which is unknown.

## EQUIPMENT

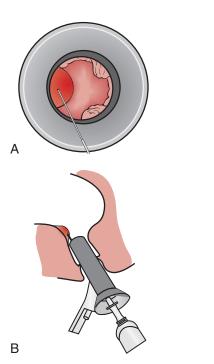

- Ives slotted anoscope
- 5-mL syringe
- 21-gauge spinal needle
- Sclerosant (sodium morrhuate, sodium tetradecyl sulfate, hypertonic saline, or phenol in almond oil)

## **TECHNIQUE.** See Figure 106-9.

- Insert the anoscope and visualize the hemorrhoid group to be injected.
- 2. Insert the spinal needle into or immediately above the hemorrhoid group in the submucosal space. Withdraw the plunger of the syringe and aspirate for blood to ensure that the sclerosant will *not* be injected directly into a vein.
- Inject 1 to 2 mL of sclerosant. A wheal should be noted during injection. Take care to inject well above the level of the dentate line.
- 4. Document the location of the injection and the amount of sclerosant used
- Reposition the anoscope to visualize the next hemorrhoid group to be treated.

# COMPLICATIONS

- The procedure is painful if the sclerosant is injected below the level of the dentate line.
- Thrombosis of internal or external hemorrhoids may occur, causing pain. Thrombosis is managed with topical creams, analgesics, and sitz baths.
- Bleeding is usually the result of injection into the mucosa rather than the submucosa. Necrosis and ulceration with bleeding

**Figure 106-9 A,** Sclerotherapy as viewed through the anoscope. If a wheal is not produced, the injection is too deep and the needle should be withdrawn. An injection that is too superficial will produce necrosis of the anal canal lining. **B,** Injection technique.

occur 2 to 3 weeks after injection. Healing usually occurs in 3 to 6 weeks.

- Abscess occurs very rarely.
- Anaphylaxis from the sclerosant is rare.
- Impotence has been reported, but the etiology is uncertain.

#### **ADVANTAGES**

- The procedure is effective.
- It can be used in a patient on warfarin.
- The equipment cost is minimal.
- It can be used concomitantly with banding or other therapies.

#### **DISADVANTAGES**

- The procedure is associated with more significant complications than other methods.
- The technique is harder to master.

**POSTPROCEDURE PATIENT EDUCATION.** See the sample patient education handouts online at www.expertconsult.com.

- Inform the patient that mild rectal discomfort may occur after treatment, and tell the patient to report any severe symptoms.
- Instruct the patient to return to the office in 4 weeks for repeat examination and further treatments if necessary.

#### Stapled Hemorrhoidopexy

Recently, stapled hemorrhoidopexy (SH or PPH, "procedure for prolapse and hemorrhoids") has been introduced as a novel method of correcting third- and fourth-degree hemorrhoids. During this procedure, a specialized stapling device reduces hemorrhoidal prolapse by excising a circumferential band of prolapsed mucosa and submucosa between the distal rectum and proximal anal canal (Fig. 106-10). This procedure interrupts the terminal branches of the hemorrhoidal arteries and resuspends the anal canal mucosa to a more physiologic location. The stapling device is know as the PPH 03 and is manufactured Ethicon Endo-Surgery, Inc. (Cincinnati, Ohio).

**INDICATIONS.** This procedure can be used with minimally symptomatic external disease. Other clinicians will perform PPH and add single- and multiquadrant excision or external hemorrhoids or tags.

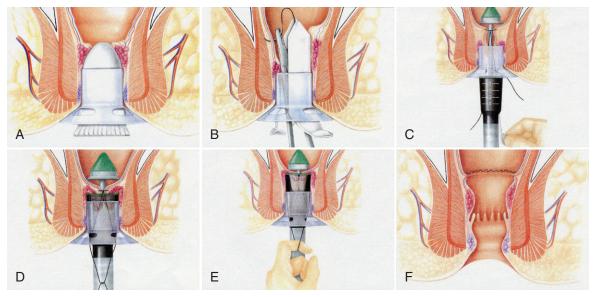

Figure 106-10 Procedure for prolapse and hemorrhoids, or stapled hemorrhoidopexy. **A**, A circular anal dilator/obturator is inserted into the anal canal to push the prolapse back and lift the hemorrhoidal tissue into place. **B**, The internal hemorrhoids are held back while a pursestring suture is prepared in the rectal mucosa/submucosa approximately 4 to 6 cm from the dentate line. **C**, A fully opened hemorrhoidal circular stapler is inserted beyond the pursestring suture. The pursestring is tied around the anvil to secure the excess mucosal tissue. With the suture threader, each limb of the suture is brought through the channel of the instrument. **D**, After the ends of the retraction suture are knotted, the stapler is tightened and gently pushed into the anal canal. Moderate traction on the pursestring must be maintained so that the prolapse is drawn into the stapler casing. **E**, The stapler is then closed completely, fired in one fluid motion, and withdrawn gently. The anal canal wall is reconnected and restored, and the hemorrhoidal artery's terminal branches, which feed internal hemorrhoids, are interrupted. **F**, Successful completion of the procedure for prolapse and hemorrhoids corrects the prolapse, restores internal hemorrhoids to their normal anatomic position, and alleviates the patient's symptoms. (From Senagore AJ, Abcarian H, Chiu YSY, Ellis CN: Current treatment options for patients with grades III and IV hemorrhoids. Contemp Surg Supplement:S5–S11, 2006.)

#### CONTRAINDICATIONS

- Anal stenosis
- Large external hemorrhoids or tags
- Gangrenous or strangulated hemorrhoids
- Perianal sepsis
- Full-thickness rectal prolapse
- Anal-receptive intercourse

#### **ADVANTAGES**

- Less postoperative pain and more rapid return to normal activities than with a surgical hemorrhoidectomy
- No external wounds to care for
- Less incontinence and constipation reported than with conventional hemorrhoidectomy

#### **COMPLICATIONS**

- Anal stenosis.
- Secondary bleeding.
- Urinary retention.
- Pelvic sepsis.
- Incontinence.
- Prolonged, intractable pain has been reported.

#### POSTPROCEDURE PATIENT EDUCATION

- There are usually no external wounds to care for. This is case dependent.
- Prescribe an oral analgesic.
- Discomfort lasts for 1 to 2 weeks.
- Warm tub soaks may relieve discomfort.
- The patient should take a bulk laxative to maintain soft stool.

#### THROMBOSED EXTERNAL HEMORRHOIDS

External hemorrhoids occur below the dentate (pectinate) line. Patients with thrombosed external hemorrhoids have a painful, tender, swollen, bluish lump at the anal orifice. If the patient is seen within 48 hours of the onset of symptoms, the thrombosed hemorrhoid should be incised or excised. After 48 to 72 hours, symptoms have usually improved and symptomatic care is recommended if the pain is minimal, especially for smaller lesions. However, if the patient is still experiencing significant pain, the hemorrhoid can be surgically relieved at any time.

There are three basic surgical approaches: (1) excise an ellipse over the clotted hemorrhoid and evacuate the clot, (2) excise the hemorrhoid completely, and (3) make a simple incision over the clot and express the contents.

# **Equipment**

- No. 11 blade and tissue scissors
- Mosquito hemostats
- Fine tissue forceps
- Lidocaine (2%) with epinephrine; 27-gauge, 1½-inch needle, and 3-mL syringe
- Antiseptic solution
- 4-0 or 5-0 absorbable suture (if closure is desired, but best if left open)

# **Technique**

See Figures 106-11 and 106-12.

- 1. Cleanse the perianal area with antiseptic solution.
- 2. Infiltrate the skin over the thrombosed external hemorrhoid with lidocaine with epinephrine (1 to 2 mL).
- 3. Excise the entire hemorrhoid as an ellipse, or *perform an elliptical excision* over the *top* of the hemorrhoid and remove the skin. Be sure to evacuate all clots.

- 4. Control any bleeding with electrocautery or silver nitrate sticks if pressure alone is not adequate.
- 5. The wound is best left open to heal by secondary intention, which it usually does without adverse sequelae. The skin edges may also be approximated with interrupted, fine absorbable suture (unless silver nitrate was used), but this is generally discouraged.
- 6. Alternatively, after anesthesia, the base of the clotted hemorrhoid can be clamped (under the clot) with a hemostat. The tissue over the hemostat is excised with a blade. With the hemostat still in place, a suture is placed proximal to the tip. If interrupted sutures are used, leave the ends of the first stitch long and use them for traction to pull down the upper portion of the incision. If a running stitch is used, the long end can be used in the same manner. Then remove the hemostat and complete the closure. This ensures that the entire excisional site has been sutured closed.
- 7. Some physicians *simply incise* over the thrombus and evacuate the clot. If this is done, it is imperative that *all* clots be removed. After the incision is made, express the clot, and then explore the cavity with hemostats to break down any septa. Another incision inside the cavity may be necessary. Frequently more than one clot will be evacuated. Reexpress the area to be sure all clots have been removed. This technique is quicker, but warn the patient that there is a higher likelihood of reaccumulation with this approach. Consider this method when the clot has been present for several days and the acute clotting process has resolved.

# **Complications**

- Bleeding
- Pain
- Recurrence
- Chronic fissure
- Infection

#### **Postprocedure Patient Education**

See the sample patient education handouts online at www.expert-consult.com.

- Recommend that the patient take sitz baths two to three times per day for 1 week.
- Oral analgesics, topical anesthetic cream/ointment (e.g., lidocaine 5%), and stool softeners are helpful.
- A follow-up examination should be scheduled for 4 weeks.
- Emphasize that the patient avoid prolonged sitting on the toilet to prevent recurrent thrombosis. Also, avoid any activity (e.g., weight lifting) that induces a Valsalva maneuver.
- Explain to the patient that a high-bulk, high-fluid diet is essential.

## **EXTERNAL HEMORRHOIDAL TAGS**

See Figures 106-13 and 106-14 (also see Chapter 108, Removal of Perianal Skin Tags [External Hemorrhoidal Skin Tags]).

External hemorrhoidal tags are usually the result of previous external hemorrhoidal disease. Occasionally, a patient has experienced a thrombosis that resolved spontaneously but the skin remains stretched out. These lesions no longer have dilated vessels and are often quite fibrotic. The major symptoms include pruritus and problems with cleanliness. Generally, when removed in the office, only one area is removed at a visit unless the attachments are quite small.

# **Equipment**

- Alcohol wipe
- 3% to 5% lidocaine with epinephrine

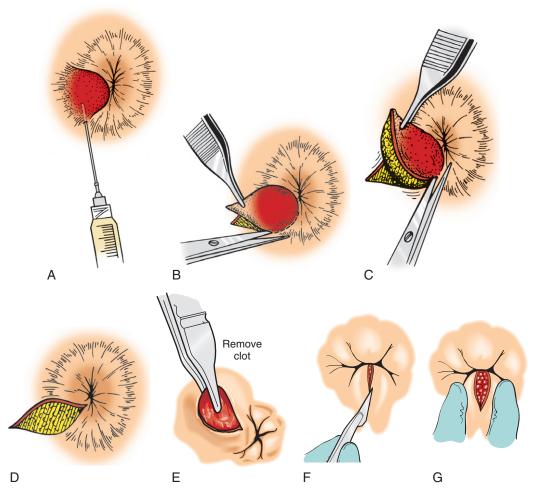

Figure 106-11 Excision of a thrombosed hemorrhoid. **A,** The area is infiltrated with 2% lidocaine with epinephrine. **B** and **C,** The thrombosed hemorrhoid is excised along with a small wedge of skin. **D,** Skin edges are sufficiently separated to permit adequate drainage, thereby preventing clot reaccumulation. They can also be closed with fine absorbable suture. **E,** Instead of removing the entire hemorrhoid, a small elliptical incision is made over the hemorrhoid and the clot is expressed. No suture closure is needed. **F,** A simple incision and drainage with expression of all clots can also be performed. Multiple clots are often present and should be removed. **G,** After the initial clot is removed, spread the incision to expose the base of the hemorrhoid to remove other thrombi. The disadvantage of this approach is that the incision can seal over, allowing the clot to reaccumulate.

- No. 15 scalpel blade
- Monsel's solution to control bleeding
- Cautery (ball electrode or bipolar forceps)
- 5% lidocaine ointment
- Ives slotted anoscope
- Lubricant
- Nonsterile gloves
- Formalin pathology jar

# **Indications**

Symptomatic as noted previously.

# **Contraindications**

The treatment is contraindicated if the patient is unwilling to tolerate pain for several days.

# **Technique**

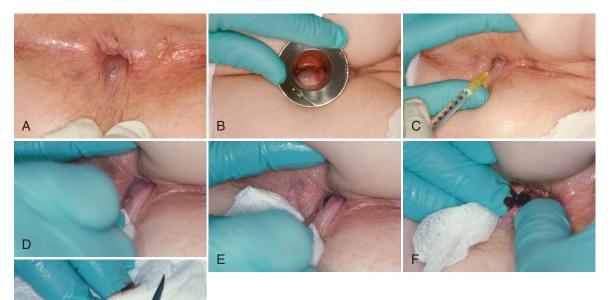

- 1. Place the patient in left lateral decubitus position. Perform digital and anoscopic examinations.
- 2. Identify the lesion to be removed and wipe with alcohol or other antiseptic.

- 3. Inject the lidocaine in a field block pattern. Be careful not to tent up the area too much under the tag, which may lead to excision of too much tissue.
- 4. If using a radiofrequency unit, set at cut and coag (level 3, or 30 W) and use either a Vari-Tip wire or a loop and remove the lesion. Control the bleeding with Monsel's solution or cautery.
- 5. Alternatives are to use a blade or scissors to remove the lesion. There may be more bleeding with this method. If the base of the tag is quite large, a hemostat can be applied and left in place for several minutes, and then the tissue excised. This ensures approximation of the skin margins. No sutures are placed because they increase the chances of infection. Control bleeding as indicated previously.
- 6. Apply antibiotic ointment mixed with 5% lidocaine ointment.

# **Complications**

- Pain
- Bleeding
- Infection
- Chronic fissure

# **Postoperative Patient Care**

Nonsteroidal anti-inflammatory drugs are the mainstay for pain control. Narcotics can cause constipation. Lidocaine 5% ointment is helpful to control and reduce abrasive rubbing of clothes or other skin. Sitz baths are very helpful and the area should be cleansed three to four times a day. It may be best to stay off work for 2 to 3 days, depending on the size of the lesion.

#### **CPT/BILLING CODES**

- 46083 Incision and drainage of thrombosed external hemorrhoid
- 46220 Excision, single anal tag
- 46221 Hemorrhoidectomy, by simple ligature (e.g., rubber band)
- 46230 Excision of external hemorrhoid tags and/or multiple papillae
- 46320 Enucleation or excision of external thrombosed hemorrhoid
- 46500 Injection of sclerosing solution, hemorrhoids
- 46600 Anoscopy
- 46934 Destruction of hemorrhoids, any method; internal (e.g., IRC)
- 46935 Destruction of hemorrhoids, any method; external
- 46936 Destruction of hemorrhoids, any method; internal and external
- 46947 Hemorrhoidopexy (e.g., prolapsing internal hemorrhoids) by stapling

**NOTE**: The last code is inappropriate when only IRC, band ligation, or sclerotherapy techniques are used for treatment of internal hemorrhoids.

#### **ICD-9-CM DIAGNOSTIC CODES**

- 455.0 Internal hemorrhoids
- 455.1 Internal hemorrhoids, thrombosed
- 455.2 Internal hemorrhoids, bleeding
- 455.3 External hemorrhoids
- 455.4 External hemorrhoids, thrombosed
- 455.9 Hemorrhoid tag

# Perianal Abscess Incision and Drainage

James A. Surrell

A perianal abscess is one of the most painful anal conditions seen in the outpatient setting. The pain of a perianal abscess is severe, disabling, and progressive, and the only relief these patients obtain is with spontaneous rupture of the abscess or when they seek medical attention for incision and drainage (I&D). The most common etiology of perianal abscess is thought to be an infection originating at the dentate line in the anal crypts (see Chapter 97, Clinical Anorectal Anatomy and Digital Examination). The infection then usually migrates through the path of least resistance to the perianal tissues, where there is a closed-space environment ideal for proliferation of this mixed bacterial infection.

The four locations where abscesses can occur and their relative incidence are shown in Figure 107-1. The most common site of an abscess in the anal area is in the perianal tissues immediately adjacent to the anal verge (60%). If the abscess is located 2 to 3 cm away from the anal verge, then it is most likely in the ischiorectal location (25%), just outside the anal sphincters. An intersphincteric abscess occurs in the intersphincteric plane, between the internal and external sphincters. An abscess in this location may not be externally visible or palpable in the perianal tissues. The pain of an abscess is present but the diagnosis will be confirmed only on digital anorectal examination, where the fluctuant mass is easily palpable. The least common abscess in this area is in the *supralevator* location, and is more correctly identified as a perirectal abscess as opposed to a perianal abscess. Most clinicians would agree that if a supralevator abscess is diagnosed, they must look for an intra-abdominal or pelvic source. A supralevator abscess may be associated with appendicitis, diverticulitis, pelvic inflammatory disease, or other pelvic or abdom-

Patients with a perianal abscess may develop an associated fever and often have a marked leukocytosis, depending on the severity of the infection. Once the diagnosis of perianal abscess is made, it is essential to proceed with adequate I&D treatment without delay. This is especially important in any patient who may be immunocompromised, is on steroids, or who has diabetes or any other debilitating comorbidity. The treatment of choice for a perianal abscess is clearly I&D—not antibiotic therapy. If adequate I&D of a perianal abscess is not performed, patients can rapidly develop severe infectious problems such as necrotizing fasciitis, which can become life-threatening, or perineal sepsis, which is a medical emergency identified with the classic triad of pain, fever, and inability to void.

#### **INDICATIONS**

Nearly every perianal abscess should be incised and drained. The only reason not to perform this procedure would be if spontaneous drainage of the abscess has occurred and if, in the judgment of the

examining clinician, adequate drainage has resulted. These abscess cavities can have multiple loculations, and if spontaneous drainage has occurred, the abscess cavity must still be explored with a digital examination or hemostats to break down any loculated areas within the abscess.

#### **CONTRAINDICATIONS**

Patients with underlying hematologic diseases may have perianal abscesses. The associated hematologic disease may include leukemia, granulocytopenia, and lymphoma. The infecting organisms seen with this type of perianal abscess may be quite different from those seen with an otherwise uncomplicated perianal abscess. In those patients with an associated hematologic disorder and a perianal abscess—for example, with leukemia under poor control—conservative treatment with antibiotics combined with local radiation therapy may be advised. Other clinicians recommend aggressive surgical management of perianal abscess in patients with hematologic disorders, but clearly this is never to be attempted in the outpatient setting.

# **EQUIPMENT**

A minor surgical instrument setup includes the following:

- Local anesthesia (2% lidocaine with epinephrine)
- 25- to 30-gauge, 1½-inch needle with 5-mL syringe
- Hemostats
- No. 11 blade
- 4 × 4 gauzes
- Penrose drain or iodoform gauze
- Suction may be needed if the abscess is large
- Surgical electrocautery unit is often helpful to achieve hemostasis at the I&D site of the infected and hyperemic tissue
- Ives slotted anoscope or various-sized Hill-Ferguson rectal retractors to facilitate visualization (available from most medical supply companies)

# PREPROCEDURE PATIENT PREPARATION

Advise the patient that, in all likelihood, rather dramatic pain relief will follow the procedure. Further advise the patient that, unless adequate I&D is accomplished, further tissue damage may result. Clearly, the most effective way to afford adequate pain relief is to drain the abscess. Recurrence, bleeding, and pain are all possible. Further work-up may also be necessary to rule out other disease processes, such as inflammatory bowel, once the infection is controlled.

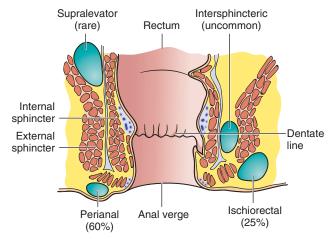

Figure 107-1 Anatomic locations of anorectal abscesses.

# **TECHNIQUE**

Patients with a perianal abscess have a clear need for prompt pain relief. Local anesthesia may be used in an attempt to anesthetize the skin at the intended I&D site, but this is often only marginally effective. The infected perianal tissues usually do not respond well to local anesthetic agents because of the highly acid environment. Either spinal or general anesthesia for this outpatient procedure may be required, depending primarily on the size of the abscess and on the specific patient circumstances. Before the actual I&D of the abscess cavity, it is appropriate, if not essential, to perform anoscopy to look for an internal opening of a fistula tract feeding the abscess cavity. The advantage of doing the anoscopy before I&D of the abscess is that, with gentle pressure on the abscess cavity, the physician may see pus expressed from an internal opening at the level of the dentate line. This then clearly establishes the diagnosis of an associated anal fistula. Textbooks of colon and rectal surgery vary widely on the incidence of associated fistula with perianal abscess, but most experts would agree that it is at least in the range of 50%.

- 1. Anesthetize the area using 2% lidocaine with epinephrine and a 27- or 30-gauge needle.
- 2. Make an incision over the fluctuant area near the anal canal in a plane radial to the circumference of the anal canal. The advantage of this type of incision is that it can be extended easily to perform anal fistulotomy if a fistula is present and if fistulotomy is indicated. Another option is to remove an ellipse of tissue such that you can easily place a gloved examining finger into the abscess cavity (if it is that large) to break down any loculations and to place drains. At this time, express all of the purulence. Cultures may be obtained at this time in the more complicated cases, if desired.
- 3. Irrigate the abscess cavity and, if deemed necessary, place a Penrose drain loosely into the abscess cavity and suture it at the skin edge level. A Penrose drain will not adhere to surrounding tissue, which makes its subsequent removal generally painless. (Alternatively, pack small wounds with 1/4- or 1/2-inch iodoform gauze.)
- 4. Remove the Penrose drain within 24 to 48 hours. With a small perianal abscess, in the office setting, the iodoform gauze is removed in 10 to 14 days. Earlier removal may lead to recurrence of the abscess.
- 5. In selected patients with a well-defined, fluctuant perianal abscess, drainage can be accomplished without anesthesia by placing a large-bore, 16-gauge needle (attached to suction or a large syringe) into the abscess (Fig. 107-2). This can be an effec-

- tive *temporizing* measure to afford dramatic and prompt pain relief if definitive surgical treatment is not readily available. The disadvantage of this needle suction technique is that evaluation for an associated anal fistula becomes more difficult.
- Postoperative antibiotics are generally not required. Consider them in immunocompromised patients or if there is extensive cellulitis or sepsis.

#### **COMPLICATIONS**

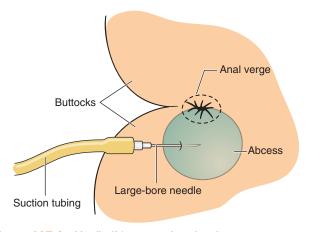

Recurrence is the most common complication after I&D of a perianal abscess. The most common cause of recurrence is an unrecognized, and therefore untreated, associated fistula. The patient with a recurrent perianal abscess must be thoroughly evaluated for the presence of an associated anal fistula. Another possible cause of recurrent perianal abscess is inflammatory bowel disease, most commonly Crohn's disease. Postprocedure bleeding and excess pain are rare complications.

#### POSTPROCEDURE PATIENT EDUCATION

After an adequate drainage procedure of a perianal abscess, advise the patient to take sitz baths for 10 to 15 minutes two to four times a day. Spend some time with the patient and his or her family to reinforce the fact that the infected wound must heal from the inside out. Most patients understand that they must keep the wound from closing with either sitz baths or showering along with the gauze packing. Explain that daily wound irrigations may be needed (if gauze is not used) to prevent the skin edges from closing prematurely before the abscess cavity has resolved. This will help to avoid a secondary infection and a recurrent abscess. These instructions usually serve as adequate motivation to follow the recommended postprocedure care.

# Removal of Perianal Skin Tags (External Hemorrhoidal Skin Tags)

James A. Surrell

Perianal skin tags represent a stretching and enlargement of the normal perianal skin (Fig. 108-1). As such, they are not true external hemorrhoids. Perianal skin tags are believed to occur as a result of large external hemorrhoids that have receded. A previously thrombosed external hemorrhoid may also leave redundant skin after resolving. Patients most often seek treatment for them when they begin to interfere with anal hygiene. It is important to note that perianal skin tags do not cause pain, bleeding, or itching. If these symptoms are present, then another source must be sought as the cause of these symptoms.

# **INDICATIONS**

- · Large perianal skin tags limiting anal hygiene
- Perianal skin tags that annoy the patient or are symptomatic (e.g., pruritus)

**NOTE:** The only time anal skin tags cause itching is when the patient is doing excessive perianal cleansing, thereby irritating the skin tag and the surrounding perianal tissues.

Generally, a conservative approach to the management of perianal skin tags is recommended because the vast majority of these benign lesions are asymptomatic. If the patient is bothered by pruritus, try local measures first. (See patient education form available online at www.expertconsult.com.)

#### **CONTRAINDICATIONS**

- If the patient with perianal skin tags complains of pain, bleeding, or itching, then another source for these symptoms must be sought. Skin tag excision will not relieve these symptoms. Even when the patient complains of pruritus "from the tag," be sure he or she is following proper hygiene practices noted in the aforementioned patient education handout because the tag itself may not be the cause of symptoms.
- If the perianal skin tags have a fleshy, edematous appearance, a diagnosis of anal Crohn's disease must be strongly considered. Nearly all patients with anal Crohn's disease will develop fleshy, edematous skin tags and have associated signs and symptoms of pain, discharge, bleeding, and atypical anal fissures (see Chapter 96, Anal Fissure and Lateral Sphincterotomy and Anal Fistula). Excision of perianal skin tags in Crohn's disease may lead to significant morbidity because of the creation of an indolent, nonhealing wound.

# **EOUIPMENT**

- 2% lidocaine with epinephrine, 3 to 5 mL
- 25-gauge, 1½-inch to 30-gauge, ½-inch needle
- 4 × 4 gauze pads
- Hemostat, straight not curved
- Pickups
- No. 10 or no. 15 blade or sharp tissue scissors (alternatively, a radiofrequency/electrocautery unit)
- Monsel's solution (ferric subsulfate)
- Cautery unit should there be bleeding
- Absorbable suture in case of uncontrolled bleeding
- Lidocaine 5% ointment
- Feminine Peri-Pad

Because the perianal skin tags are external to the anal canal, no anal retractor is needed. Any standard surgical forceps are adequate to grasp the skin tag, which is usually removed with electrocautery. The electrocautery unit should have both coagulation and cutting capability. (See Chapter 30, Radiofrequency Surgery [Modern Electrosurgery], and Chapter 149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia, for listings of suppliers of various modern electrosurgery units.) Alternatively, the lesion can be excised with sharp tissue scissors or a knife blade, but this will increase the likelihood of bleeding.

# PREPROCEDURE PATIENT PREPARATION

Most patients should be discouraged from having their perianal skin tags excised. Because perianal skin tags per se usually cause no significant symptoms, question the patient in depth about his or her reasons for wanting the skin tags excised. Advise the patient that there will be some mild to moderate "burning" postoperative pain at the site of the excision for up to 2 weeks, possibly more. Postoperative bleeding is usually negligible but can be a problem, and infection is rare because the cauterized operative site is usually left open. The chances for infection increase if the site is sutured (Vicryl, chromic).

#### **TECHNIQUE**

- 1. Place the patient in the left lateral decubitus position on the procedure table.
- Înfiltrate the base of the skin tag with approximately 1 mL of local anesthetic (e.g., 2% lidocaine with epinephrine). To minimize discomfort, inject the anesthetic solution (at room

Figure 108-1 Large perianal tag.

temperature) very slowly at the base of the skin tag with a 25- or 30-gauge, ½-inch hypodermic needle. When performed properly, this injection technique affords minimal discomfort to the patient. Do not use too much volume because this will distort the area to be excised and may leave an excessively large wound. Alternatively, do a field block around the lesion to maintain undisturbed anatomy near the tag.

- 3. After approximately 1 minute, grasp the skin tag with a 4 × 4 gauze pad between the thumb and index finger and compress it to reduce the edema caused by infiltration of the local anesthetic. This also restores the skin tag to its "normal" anatomy so the site of excision can be identified properly.
- 4. Grasp the skin tag with forceps (which will confirm that appropriate anesthesia has been induced) and hold it perpendicular to its base on the perianal skin. Care must be taken not to put any undue tension on the skin tag because this will also serve to "tent up" and broaden the base of the skin tag and create an excision site that is much larger than needed.
- 5. Excise the skin tag, using the electrocautery unit in the cutting or blend mode. The site of excision should be approximately 3 mm above the normal perianal tissues because there will be electrocautery tissue destruction below the site of excision. If the skin tag is held taut or excised right at the level of the perianal skin, the resulting wound defect and patient discomfort will be greater than needed (Fig. 108-2).
- Cauterize any residual small bleeding sites. No more than three perianal skin tags are recommended to be excised during any one procedure.

Figure 108-3 Clamping the base of tag for hemostasis.

Figure 108-4 Scalpel excision of tag.

Figure 108-2 Removing perianal tag using cutting electrosurgery.

Figure 108-5 Appearance immediately after removing tag.

Figure 108-6 Final result. No sutures are used for closure.

- Leave the site of excision open because suture closure contributes to an increase in postoperative pain and a greater likelihood of perianal abscess.
- 8. For larger tags, apply a straight hemostat at the base of the lesion, being careful not to grasp too much tissue. Leave it in place several minutes to control potential bleeding. Shave off the excess tissue using desired method. Remove clamp (Figs. 108-3 to 108-6).
- 9. Control bleeding.
- 10. Apply antibiotic ointment to soothe the area and prevent it from drying/sticking to clothing.
- 11. Give the patient a Peri-Pad to prevent blood from reaching clothing.
- 12. It is probably best to excise only one tag at a time if the procedure is being done in the office. This limits pain and the potential for bleeding, and decreases tension on the healing wound. This is especially true with larger-based lesions.

#### **COMPLICATIONS**

- A perianal abscess can develop at the site of excision of a skin tag, although this is uncommon and occurs less than 1% of the time. If an abscess does occur, appropriate incision and drainage will be necessary.
- If the skin tag excision site is very close to the anal verge, a chronic fissure may develop, although this is also very uncom-

- mon. Should a fissure develop and persist, lateral internal sphincterotomy would be recommended.
- Perianal cellulitis can rarely occur. Should this be diagnosed, appropriate antibiotic therapy should be instituted. Topical antibiotics can be used with the lidocaine ointment to alleviate this potential.
- Bleeding or hematoma may occur within the first 24 hours after the procedure. Usually, applying ice or having the patient sit on a rolled-up washcloth provides enough pressure to tamponade a bleeder. Occasionally, a suture(s) may be required.

Excision of skin tags should not alter anal continence because of the lack of involvement of this procedure with the anal sphincters.

# POSTPROCEDURE PATIENT EDUCATION

Wash the area gently three to four times a day and after defecation with mild soap and water. Lidocaine ointment 5% or an antibiotic ointment may be used to decrease discomfort. Prescribe a nonconstipating pain medication (e.g., ibuprofen). Further advise the patient to follow a high-fiber diet with commercial fiber supplements and four to six glasses of water per day. Time off from work is usually minimal and would range from 0 to 3 days, depending on the extent of excision. Total healing time may take up to 6 weeks for complete new skin coverage. Perianal discomfort is usually present for 1 week or less.

# PILONIDAL CYST AND ABSCESS: CURRENT MANAGEMENT

James A. Surrell

A bilonidal cyst or abscess is located in the gluteal crease, usually within 5 to 10 cm of the anal verge. This lesion was originally described in the mid-1800s, and there has been considerable debate in the literature over whether it is an acquired or a congenital lesion. Most experts now believe that this is an acquired lesion resulting from penetration of the skin at this level from shafts of hair. A pilonidal sinus frequently contains multiple hairs that are microscopically noted to be tapered at both ends like shed hairs. The existence of hair follicles in the wall of the pilonidal sinus tract has never been demonstrated conclusively. Pilonidal sinus and abscess is a disease of the younger population, and 75% of cases are seen in males. Most patients develop symptoms of pilonidal disease between the ages of 20 and 25 years. A typical patient develops an abscess or experiences recurrent infection and drainage at the base of the spine. The disease is characterized by the development of multiple sinus tracts in this location.

Examination of the patient with suspected pilonidal disease generally reveals an area of inflammation in the midline of the gluteal crease, with one or more sinus openings (Fig. 109-1). The openings may be slightly off the midline. Careful inspection of this site often reveals loose hairs projecting from the sinus openings. Note that these hairs are not growing in the pilonidal sinus cavity, but rather are shed loose hairs that have migrated to this dependent site in the gluteal crease. If the pilonidal sinus has an associated abscess, the patient will complain of pain and the examiner may note swelling and erythema at this site. Spontaneous and ongoing drainage is the common indicator, however, and if an abscess is present it is usually small. As a general guideline, if the patient gives a history of recurrent infection at the base of the spine, this in itself is almost diagnostic of a pilonidal sinus disease. Some difficulty in diagnosis may occur if the pilonidal sinus is located in the more caudal position closer to the anal canal. This position raises the possibility of an anal fistula as the cause of the infection. If, however, hairs are found in the lesion, this offers convincing confirmatory evidence that the physician is dealing with a pilonidal sinus or abscess.

# **INDICATIONS**

Surgical treatment should be performed for the following:

- Acute abscess formation in the superior gluteal crease area (simple incision and drainage [I&D] may be adequate but recurrences are common).
- Patients with a history of recurrent infections and drainage at the base of the spine are better treated with complete excision of the area. (Antibiotic therapy should be considered only as temporizing and palliative because recurrence will be the rule until adequate I&D or excision is accomplished.)

#### **CONTRAINDICATIONS**

- Patient with a paucity of symptoms, such as only minimal drainage with little or no discomfort or inflammation occurring perhaps only once or twice per year
- History of bleeding disorder

# **EQUIPMENT**

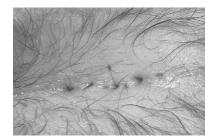

- Local anesthesia.
- No special equipment is necessary to perform a simple I&D; a no. 11 blade is adequate.
- Only a minor surgical setup is required for excision plus a dermal curette

# PREPROCEDURE PATIENT PREPARATION

The procedure of choice is I&D; for recurrent abscesses or persistent draining, excision of the involved area is needed. The wound is left open to heal by secondary intention. With this technique the patient needs to be informed of a prolonged healing time. The wounds are not at all disabling and they can be expected to close, but it takes 8 to 12 weeks. Other options for treatment of pilonidal disease must be reviewed to include excision with primary closure, as well as using a skin flap or other plastic procedures for more extensive and complex involvement.

# **TECHNIQUE**

A simple I&D may be all that is needed for a small abscess or firsttime presentation. For recurrent disease, perform an elliptical incision at the site of the pilonidal disease to include the obvious sinus tract(s) (Fig. 109-2). The lateral and deep margins should extend to noninfected tissue that appears healthy. This procedure can be performed under local anesthesia (with or without intravenous sedation) or under general anesthesia in the operating room. Because of the proximity of the infected site, spinal anesthesia is not recommended. Thoroughly inspect the wound during the procedure, and curette all chronically infected granulation tissue so that the remaining wound defect is lined with healthy-appearing tissue with no obvious remaining sinus tracts. If the resultant wound defect is not too deep, depending on the extent of the disease and the body habitus of the patient, consider marsupialization of the wound by tacking the skin edges to the base of the wound with an absorbable running simple suture (Fig. 109-3) to help prevent premature secondary wound closure. Total procedure time is generally 30 minutes or less.

**Figure 109-1** Multiple (six) pilonidal sinus openings in the natal cleft. (From Thomson J: Disorders of the anus and anal canal. In Misiewicz JJ, Bartram CI, Cotton PB, et al [eds]: Slide Atlas of Gastroenterology. London, Gower Medical, 1986.)

# **COMPLICATIONS**

Clearly, the most common complication of surgery for pilonidal disease is *recurrence*. The results are variable, but most physicians report that the open technique has less of a recurrence rate than the closed technique. The obvious disadvantage to the open technique is the prolonged healing time, but these wounds generally do not afford significant morbidity to the patient during this longer healing process. With the open technique, *bleeding*, *excessive pain*, and *infection* are rare. Two randomized trials have compared a surgical "flap" procedure with primary closure. Both studies found the flap procedure to be superior in terms of pain, healing, complications, and return to work, but these surgical procedures are more extensive and should be performed only by an experienced surgeon. The flap procedure may be the best option for persistently recurrent pilonidal disease.

#### POSTPROCEDURE PATIENT EDUCATION

If the procedure is performed with the pilonidal disease excised and the wound left open, instruct the patient on proper wound management. An open wound should be cleansed several times daily with soap and water, either by showering or other irrigation.

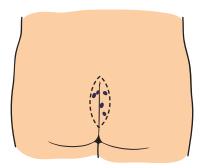

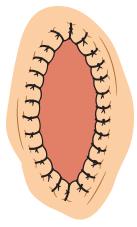

Figure 109-2 Area of elliptical excision for pilonidal sinus.

**Figure 109-3** Marsupialization after excision of pilonidal sinus, closed with interrupted absorbable sutures.

During the early stages of wound healing, the wound is packed with moistened gauze sponges changed twice daily. During the early phases of postprocedure recovery, examine the patient on a weekly basis to assess adequate progress. At this time, if hair regrowth is occurring, wound edges may be shaved. Every effort to prevent loose hairs from entering the healing wound should be made. Instruct the patient on the concept of the wound's healing from the inside out so that premature skin bridging does not occur before the entire cavity is obliterated. Typical time off from work is approximately 1 week.

# BLADDER CATHETERIZATION (AND URETHRAL DILATION)

Robert E. James • Grant C. Fowler

Bladder catheterization may be performed for diagnostic or therapeutic indications (or both). This procedure is the most common retrograde manipulation performed in the urinary tract. Familiarity with the anatomy of the urethra and the available catheters will increase the ease and success of this procedure. Like all procedures in urology, this should be performed in a gentle fashion; instruments need not be forced. This is considered by patients to be among the five most painful emergency procedures, so, when possible, anesthetic jelly should be used. Indications and contraindications for infants and children are basically the same as for adults.

In the adult male patient, there are two points where obstruction is commonly encountered when passing a catheter. The first is at the point of acute upward angulation located between the bulbous and the membranous urethra. The second is at the bladder neck, where a bladder neck stenosis or an enlarged median lobe of the prostate gland may be present (Fig. 110-1). In younger male patients, urethral folds or valves may resist the insertion of a catheter.

In the female patient, the urethra is much shorter, averaging only 2 inches in an adult. The angle between the urethra and the bladder neck increases with age. Consequently, in the older patient, the urethra is normally directed toward the sacrum, whereas in the younger patient it is angled toward the umbilicus. Keeping these urethral angles in mind will improve the clinician's technique, thereby increasing patient comfort and facilitating passage of the catheter. Catheter size is measured in French units. As the number increases, the size increases (i.e., a 16-Fr catheter is larger than a 12-Fr catheter). One "French unit" is approximately 0.33 mm.

#### **INDICATIONS**

#### **Short-Term Catheterization**

- Acute urinary retention
- Collection of uncontaminated urine specimen for analysis, culture, and sensitivity (especially for female patients)
- Diagnostic studies of the lower urinary tract (e.g., cystogram, voiding cystourethrogram, urodynamics)
- Monitoring of urinary output
- Measurement of postvoid residual urine volume
- Irrigation of the bladder or instillation of medication
- Surgery on the urinary tract or adjacent structures
- Bladder drainage during and after surgical procedures requiring anesthetics
- Intermittent (in and out) catheterization for neurogenic bladder

#### **Long-Term Catheterization**

- Chronic urinary retention
- Neurogenic bladder in patient with inability to intermittently self-catheterize

- Incontinence with complicating skin breakdown
- As a comfort measure for terminally ill or severely disabled patient with incontinence

**NOTE:** A Cochrane review found that patients requiring catheterization for up to 14 days had less discomfort, bacteriuria, and need for recatheterization when suprapubic catheters were used compared with urethral catheters. Similarly, in a recent meta-analysis of patients having abdominal surgery, suprapubic catheters were found to cause less bacteriuria and discomfort and were preferred by patients (see Chapter 113, Suprapubic Catheter Insertion and/or Change).

#### **CONTRAINDICATIONS**

- Known or suspected urethral disruption resulting from pelvic trauma (be suspicious if there is blood at the urethral meatus, a perineal hematoma, or a high-riding prostate)
- Recent reconstructive surgery of the urethra or bladder neck (relative contraindication, but should consult urology)
- Known urinary tract obstruction, such as a urethral stricture (relative contraindication, may be able to dilate)
- A combative or uncooperative patient (relative contraindication; see Chapter 2, Procedural Sedation and Analgesia)
- An acute infection of the prostate and/or urethra (relative contraindication)

#### **EQUIPMENT**

- Urethral catheters
  - Robinson catheter: A straight, rounded-tip catheter used for short-term catheterization; one version is the red rubber catheter. Low-friction, hydrophilic-coated catheters have been found to increase patient satisfaction and decrease urinary tract infection and hematuria in patients who practice clean, intermittent self-catheterization.
  - Foley catheter: A straight, self-retaining catheter that may have two or three lumina. While urine flows through the main, large lumen, and the secondary, smaller lumen is connected to a port used to inflate the retaining balloon (Fig. 110-2A), a Foley with a third lumen may be selected if irrigation will be necessary, such as for ongoing hematuria. A 16- to 18-Fr Foley catheter may be used for adults or adolescents (smaller sizes are used for infants and children) who require either a temporary or a chronic indwelling catheter. Foley catheters have short- or long-nose tips. Silicone or silicone-coated versions tend to be preferred over rubber catheters for long-term use because they produce less tissue reaction, have less encrustation, and have a larger lumen. By design, the retaining balloons can be overinflated, if necessary, to twice their stated capacity.

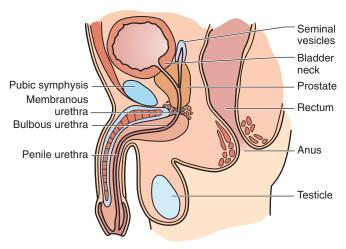

Figure 110-1 Male urethral anatomy.

- Coudé catheter: This catheter is similar to a Foley catheter with some slight variations: the terminal 2 inches are curved upward (coudé is the French word for "elbow"; Fig. 110-2B) and there is a small ball on the tip. This catheter is used in adult men for whom a Robinson or Foley catheter cannot be inserted because of an enlarged median lobe of the prostate or an elevated bladder neck. Some clinicians advocate using a coudé catheter in all men older than 50 years of age. Coudé catheters are available with or without a self-retaining balloon. A 16- to 18-Fr catheter is normally used.
- Filiforms and followers: Filiforms are very thin, very pliable solid catheters that range in size from 1 to 6 Fr and are used to dilate a male urethral stricture. They may be straight or pig-tailed, or have a coudé tip, but they all have a female screw tip on the opposite end for attachment of followers. Followers are larger in diameter (12 to 30 Fr), have a male screw tip to attach to the filiforms, and are usually hollow with an open end. (Avoid the solid or closed-end followers; it may be impossible to tell when the forward tip has reached the bladder, so significant damage can occur. With the hollow, open-ended followers, you can tell when you are in the bladder because urine starts to flow.) Both filiforms and followers have a smoothcoated surface and are made of plastic or have a woven fiber core.

**NOTE:** Silastic catheters are available for latex-sensitive patients. Although a Cochrane review found that silver alloy-impregnated

- catheters compared with standard catheters were associated with decreased rates of urinary tract infections, this is considered controversial and they are expensive.
- Lubricant: either a water-soluble lubricant (K-Y Jelly) or a lubricant with a local anesthetic (2% lidocaine jelly) may be used.
  When available, the latter is preferred; 10 mL is sufficient for adult and adolescent female patients and 10 to 20 mL for adult and adolescent male patients, with smaller amounts for infants and children.
- Sterile towels and gloves
- Sterile cotton-tipped applicators
- Antiseptic solution
- Closed urinary drainage system (bedside overnight drainage bag, leg bag, or abdominal drainage system [belly bag])

#### PREPROCEDURE PATIENT PREPARATION

The specific indications for catheterization, as well as the risks, benefits, alternatives, and technique, should be reviewed with the patient, parent, or caregiver. Long-term catheter care should be discussed if the catheter is to remain in place. (See the sample patient education form available online at www.expertconsult.com.) Informed consent is not always necessary for catheterization; however, at least verbal consent should be obtained and documented in the chart. Self-catheterization should be taught to the patient (or parent or caregiver) with the neurogenic bladder. Adequate lubrication and sufficient frequency are more important than sterile conditions if the patient is going to intermittently self-catheterize. If dilation is necessary, the patient should also understand the risks, benefits, alternatives, and technique. Informed consent should be obtained. It may be comforting to reassure the patient that everything possible will be done to maintain his or her modesty.

#### **TECHNIQUE**

#### **Bladder Catheterization**

- The female patient is placed in the dorsal lithotomy or the supine position with the legs abducted (i.e., frog-legged position). The male patient is placed in the supine position; the legs may be either abducted slightly or straight. The clinician should observe universal blood and body fluid precautions.
- 2. Identify the urethral meatus. For men, the penis should be grasped by the clinician's nondominant hand and positioned pointing toward the umbilicus. Although the meatus should be easily identified in the circumcised man, gentle retraction of the foreskin (prepuce) may be necessary to identify the meatus in the

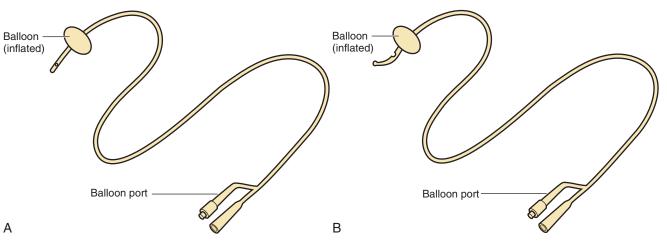

Figure 110-2 A, Foley catheter with balloon inflated. B, Coudé catheter with balloon inflated.

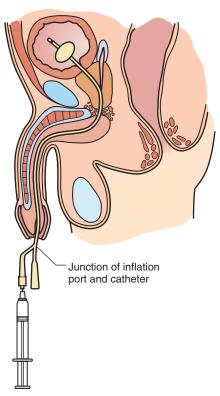

uncircumcised man. Lateral and outward traction on the labia by the clinician's nondominant hand may help identify the meatus in women. Applying downward pressure with the posterior bill of a vaginal speculum may also be helpful in women. In female infants or girls, hymenal folds may obscure the meatus, but again, lateral traction by the nondominant hand will usually help identify the meatus. If not, downward pressure with a cotton-tipped applicator placed over the introitus will usually improve visualization. Women who will be self-catheterizing can be taught to identify the meatus with a mirror. For repeat catheterizations in women, a finger inserted into the vagina can help guide the catheter.

Cleanse the urethral meatus and surrounding area with antiseptic solution, and isolate the genitalia with sterile drapes or towels. Maintain sterile technique throughout the remainder of the procedure.

**NOTE:** Bladder catheterization is considered by patients to be among the top five most painful emergency procedures. If possible, anesthetic jelly should be used.

- 4. Insert the lubricant into the urethra with a syringe. If anesthetic jelly is used, leave it in place for approximately 5 to 10 minutes (longer is better to maximize effect). Some manufacturers place the lubricant in a syringe with a smooth conical end that can be inserted into the urethra. Otherwise, draw it into a 10-mL syringe. Place the end of the syringe (without a needle) gently inside the urethral meatus and inject the jelly into the urethra. Less lubricant is needed for infants, children, and women because the urethra is shorter. An alternative to injecting anesthetic jelly into the female urethra is to place it on a sterile cotton-tipped applicator and insert it gently into the urethra. This method allows the clinician to also determine the angle of the urethra to follow for later insertion of the catheter. After injecting the jelly, the male patient should be asked to compress the mid-urethra between his index finger and thumb to prevent the jelly from leaving the urethra.
- 5. Insertion technique for male and female patients:
  - For adult or adolescent female patients, select a 16- or 18-Fr Foley or Robinson catheter (use appropriately sized pediatric feeding tubes in female newborns and infants; smaller Foley or Robinson catheters can be used in larger girls). Following the anticipated course of the urethra, pass the catheter into the bladder. Catheter placement is confirmed when urine is obtained, and this is usually after advancing about 3 inches in adults (less for infants and children). For a Foley catheter, the balloon may be inflated with 5 mL of normal saline or water. The catheter is then gently pulled outward until the balloon rests against the bladder neck.
  - For adult or adolescent male patients younger than 50 years of age, a 16- or 18-Fr Foley or Robinson catheter may be used (use appropriately sized pediatric feeding tubes in male newborns and infants, smaller Foley or Robinson catheters in larger boys). With the nondominant hand, hold the penis taut while directing it toward the umbilicus in order to straighten the urethra. With the dominant hand, pass the catheter into the bladder the full length, up to the junction of the Foley catheter and the inflation port for the balloon (Fig. 110-3), or until it reaches the hub of a Robinson catheter.

**CAUTION:** In male patients, if the Foley is not passed all the way to the port, the balloon may be inflated within the urethra, causing significant damage. The balloon is normally inflated with 5 mL of normal saline or water. If the balloon does not inflate easily, or if the patient experiences discomfort in the perineum or penis as the balloon is being inflated, you should suspect that the balloon is located within the urethra. In such a case, the balloon should then be deflated and the catheter reinserted.

**Figure 110-3** In the male patient, the Foley catheter is passed into the bladder until the junction of the catheter and inflation port for the balloon is met.

Once the balloon has been inflated, the catheter is then gently pulled outward until the balloon rests against the bladder neck.

- For male patients older than 50 years of age, consider a coudé catheter. The curve at the tip of the catheter should be directed at the 12 o'clock (anterior) position. This will permit the catheter to glide over an enlarged median lobe of the prostate gland or an elevated bladder neck. If the catheter does not pass easily, it should be removed and the procedure repeated. Occasionally, the tip of the catheter will rotate as it is being inserted. If this occurs, the catheter will not pass through the prostatic urethra into the bladder. If you cannot pass a 16-Fr Foley or coudé catheter into the male urethra, there is usually a urethral stricture, bladder neck stenosis, or very large median lobe of the prostate gland. Or, if the prostatic urethra has been previously resected, the tip of the catheter may hang up at the widened outlet of the prostatic urethra. In any of these cases, you may consider using a 12-Fr Foley or coudé catheter. The catheter tip may be caught in a posterior urethral fold, right before it can enter the prostatic urethra. Upward pressure with three fingers from the nondominant hand on the perineum, between the scrotum and the rectum, may direct the catheter tip upward enough to enter the urogenital diaphragm on its way into the prostatic urethra. Alternatively, if the patient has an enlarged prostate, directing the catheter tip into the prostatic urethra with the dominant hand while a gloved finger from the other hand is in the rectum may also be helpful. If the smaller catheter does not pass after these maneuvers, either dilation with filiform and followers is necessary or a urology consultation should be sought.
- Once in place, the catheter needs to be secured to the leg with tape or other means to prevent trauma to the urethra. If urine does not flow freely, the tip of the catheter may be obstructed by

lubricating jelly. Suprapubic pressure on a full bladder will usually flush the lubricant from the lumen. If the bladder is not full, gentle flushing from below with a 60-mL syringe full of sterile saline may open the lumen. It may take more than one syringe full in a dehydrated patient, but there should be return of fluid with gentle aspiration after injecting sterile saline. If not, remove the catheter from the urethra and repeat the procedure.

#### **Difficult Catheterizations**

**WOMEN.** Postmenopausal women with a narrow introitus, obese women, or women with a recessed or high-riding urethra may be very difficult to catheterize because the urethral meatus is difficult to visualize. In these cases, the following technique is usually successful. After preparing the patient as previously described, identify the urethral meatus with the tip of one of your index fingers. Then, slide a 16-Fr catheter along the index finger and into the urethra. If this cannot be accomplished, the patient may have a stenotic meatus. Applying the same technique, use a 12-Fr Foley or coudé catheter. If this attempt is unsuccessful, a urology consult is advised.

MEN. In uncircumcised male patients, to avoid the complication of a paraphimosis, always reduce the foreskin after catheter placement. In men with a severe phimosis, the foreskin cannot be retracted enough to see the urethral meatus. If the os of the foreskin is large enough to pass a catheter, you may be successful using the following technique. Fix the glans penis in its normal position with the meatus at the 6 o'clock position. Using a coudé catheter, rotate the catheter tip to the 6 o'clock (posterior) position. The tip of the catheter will be directed through the os of the foreskin in this position. Once the catheter has entered the urethra, it may be rotated until the tip is pointed up, to the 12 o'clock position. The catheter may then be advanced into the bladder. If the os of the foreskin will not permit the passage of a catheter, a dorsal slit of the foreskin may be performed (see Chapter 119, Dorsal Slit for Phimosis) and the catheter inserted. Otherwise, a suprapubic catheter may need to be inserted. To minimize the risk of stricture formation in male patients with a long-term indwelling catheter, the catheter should be secured to the anterior abdominal wall (i.e., abdominal drainage system or belly bag).

The optimal amount of time to leave a catheter in place for men with benign prostatic hyperplasia (BPH) is unknown. For men catheterized to relieve acute urinary retention due to BPH, up to 70% will have recurrent urinary retention within a week if the bladder is simply drained. However, the use of  $\alpha$ -adrenergic blockers (e.g., alfuzosin, tamsulosin) for 3 days starting at the time of catheter insertion has been shown to increase the likelihood of a successful voiding trial without a catheter at 2 to 3 days after catheter removal. American Urological Association (AUA) guidelines recommend at least one attempted trial of voiding after catheter removal before considering surgical intervention. Prevention of acute urinary retention in BPH may be achieved by long-term treatment (4 to 6 years) with dutasteride, finasteride, or a combination of finasteride and doxazosin. The AUA guidelines recommend using only the 5- $\alpha$ -reductase inhibitors finasteride and dutasteride in men with demonstrable prostate enlargement by digital rectal examination.

#### Filiforms and Followers

After unsuccessful Foley and coudé catheterization attempts in male patients these methods are tried.

- Reinstill anesthetic jelly into the urethra of the patient who has already been prepared and draped for prior catheterization attempts.
- 2. With the nondominant hand, hold the penis taut while directing it toward the umbilicus in order to straighten the urethra. With

the dominant hand, grasp a filiform, dip it into anesthetic jelly, and gently insert it into the urethra. Advance the filiform into the urethra until resistance is met. The filiform should be rotated slightly while it is being advanced. Grasp a second filiform, dip it into anesthetic jelly, and advance it likewise into the urethra, while rotating it, until resistance is again met. Attempt to advance the first filiform further. If the first filiform will not advance, insert a third filiform after dipping it in anesthetic jelly, and advance it with slight rotation until it meets resistance. Attempt to advance the first and second filiforms, again. At this point, the filiform tips are either in a false lumen or the resistance is due to a fold or stricture. Inserting additional filiforms will either dilate the stricture or pass the fold or false lumen. Continue to insert filiforms, while each time attempting to advance the previously inserted filiforms, until one advances. Advance this filiform until only approximately 1 inch remains outside the penis. Remove all other filiforms except this one.

- 3. Lubricate a follower catheter and attach it to the inserted filiform. Use only a hollow, open-ended follower catheter so that you can tell when the bladder has been reached or entered. When the bladder has been reached by the follower, urine should flow through it spontaneously. Gently advance the follower into the bladder until only 1 or 2 inches remains outside the penis. (The tip of the filiform will curl up inside the bladder for the follower to advance.) If resistance is met, withdraw the tip connected to the filiform until it is an inch or more outside the penis. Select, lubricate, and attach a follower that is 1 or 2 Fr smaller than the previous one, and attempt to insert this gently into the bladder. Continue this process until a follower is able to be inserted into the bladder (i.e., up to the point where only 1 or 2 inches remains outside the penis). The urethra may then need to be dilated using the process described in the next step.
- 4. If the follower catheter is 16 or 18 Fr in diameter, remove it and insert a Foley catheter. If it is less than 16 Fr, the urethra must be dilated. Withdraw the tip connected to the filiform until it is 1 or 2 inches outside the penis. Select, lubricate, and attach a follower that is 1 or 2 Fr larger than the previous one, and attempt to gently insert this into the bladder. Continue this process until a 16- or 18-Fr follower can be inserted and then converted to a Foley.

#### **Catheter Management**

With indwelling catheters, many patients experience discomfort at the junction of the urethral meatus with the catheter. This may be mitigated by applying petroleum jelly or vitamin E ointment to the meatus daily. (Otherwise, daily meatal care should be avoided because it has been associated with increased risk of infection.) Chronic indwelling catheters are usually replaced every 6 weeks, or sooner if not draining properly. Robinson and non–self-retaining coudé catheters need to be secured to the penis. Clinicians should note that tape should never be applied circumferentially around the penis because it may cause ischemia. Instead, three thin strips of tape applied along the penis and attached to the catheter will usually prevent inadvertent removal.

#### **Antibiotic Therapy**

If a urinary tract infection is suspected or the patient has a history of mitral valve prolapse, valvular heart disease or replacement, a penile prosthesis, an artificial urinary sphincter, or a recent prosthesis such as a total knee or joint, a urine culture and sensitivity should be obtained and the patient placed on a broad-spectrum antibiotic for at least 3 days. If the patient is not allergic to fluoroquinolones, ciprofloxacin or levofloxacin is an appropriate choice. Alternatively, an intravenous dose of a cephalosporin, quinolone, or other antibiotic that covers skin and perineal flora may be given just before inserting the catheter.

# Box 110-1. Centers for Disease Control and Prevention Guidelines for Prevention of Catheter-Associated Urinary Tract Infection

#### Category I: Strongly Recommended

Catheterize only when necessary.

Educate personnel in correct techniques of catheter insertion and care.

Emphasize handwashing.

Insert catheter using aseptic technique and sterile equipment. Secure catheter properly.

Maintain closed sterile drainage.

Obtain urine specimens aseptically.

Maintain unobstructed urine flow.

#### Category II: Moderately Recommended

Periodically reeducate personnel in catheter care.

Use smallest suitable catheter bore.

Avoid irrigation unless needed to prevent or relieve obstruction.

Refrain from daily meatal care.

Do not change catheter at arbitrary intervals.

From Cravens DD, Zweig S: Urinary catheter management. Am Fam Physician 61:369–376, 2000. Information from Wong ES: Guideline for prevention of catheter-associated urinary tract infections. February 1, 1981. Available at http://aepo-xdv-www.epo.cdc.gov/wonder/prevguid/p0000416/p0000416.asp. Accessed June 20, 2008.

#### **COMPLICATIONS**

- Urinary tract infection (see Box 110-1 for prevention guidelines)
- Transient hematuria
- Creation of a false passage or perforation resulting from the use of a small catheter or excessive force, or the presence of a urethral stricture
- Conversion of a partial urethral tear into a complete tear in a trauma patient with urethral injury
- Urethral stricture
- Obstruction of flow
- Epididymitis, pyelonephritis, and urosepsis are often seen with prolonged catheterization. Increased mortality was found in nursing home patients with an indwelling catheter at 1 year, but that statistic is probably confounded by other factors such as protein-calorie malnutrition.

#### **CPT/BILLING CODES**

- 51700 Bladder irrigation, simple, lavage and/or instillation
- 51701 Insertion of non-indwelling bladder catheter (e.g., straight catheterization for residual urine)
- 51702 Insertion of temporary indwelling bladder catheter; simple (e.g., Foley)
- 51703 Insertion of temporary indwelling bladder catheter; complicated (e.g., altered anatomy, fractured catheter/balloon)
- 53620 Dilation of urethral stricture by passage of filiform and follower, male; initial

#### **ICD-9-CM DIAGNOSTIC CODES**

- 344.61 Neurogenic bladder, with cauda equina syndrome
- 596.0 Bladder neck obstruction, acquired
- 596.54 Neurogenic bladder, NOS
- 598.1 Urethral stricture, caused by trauma
- 598.9 Urethral stricture, unspecified
- 599.60 Urinary obstruction, unspecified
- 600.0 Prostatism, hypertrophy (benign) of prostate
- 600.91 Hyperplasia of prostate, unspecified, with urinary obstruction
- 602.8 Prostatic stricture
- 605 Phimosis
- 625.6 Stress urinary incontinence, female
- 753.6 Bladder neck obstruction, congenital
- 788.20 Urinary retention or stasis, unspecified
- 788.30 Urinary incontinence, unspecified
- 788.32 Stress urinary incontinence, male

## DIAGNOSTIC CYSTOURETHROSCOPY

Grant C. Fowler

The construction of the cystoscope has progressed from the original tube-and-candle, first described in the early 1800s, to the flexible fiberoptic cystoscope available today. The standard rigid cystoure-throscope is composed of three components: the telescope, the sheath, and the bridge. (Rigid urethroscopes are also available, designed exclusively for evaluation of the urethra, and are a modification of the cystoscope.) Once the sheath is in place, the telescope can be removed and changed as needed for different lenses to view different aspects of the bladder. Various instruments useful for procedures (e.g., biopsy, cautery, injection), both rigid and flexible, can also be inserted.

Unlike the rigid cystoscope, the flexible cystoscope combines the optical systems and irrigation/working channel into a single unit. The flexible cystoscope also has a smaller diameter and a tip that can be deflected as much as 290 degrees in a single plane; it can be used without a working sheath, and is generally more comfortable for the patient. The patient can be in the recumbent position as opposed to the dorsal lithotomy position. This makes it ideal for use in the office or outpatient setting. However, the image from a flexible cystoscope is not as clear as that obtained with a rigid cystoscope, and because the diameter of the flexible cystoscope is smaller, operative and diagnostic procedures are limited by the decreased capacities of the irrigating and working channels. Because there is no sheath, the flexible cystoscope has to be removed completely to change the lens, and reinserted to assess residual urine and to reevacuate the irrigant. Therefore, the flexible cystoscope is used more commonly in the office setting for routine diagnostic viewing of the bladder and urethra (hematuria or tumor surveillance, double-I stent retrieval) as opposed to operative procedures. That said, either type of cystoscope, rigid or flexible, can be useful in the diagnosis of various conditions ranging from urinary incontinence to pain syndromes.

**EDITOR'S NOTE:** It might be helpful to review Chapter 110, Bladder Catheterization (and Urethral Dilation), along with this chapter.

#### **INDICATIONS**

- Urethral stricture or diverticulum on radiograph (for diagnostic or therapeutic purposes; e.g., using the rigid cystourethroscope or urethroscope, a cold knife incision of a limited stricture can be performed or a catheter placed into a diverticulum for localization during open surgical repair)
- Suspected urethral calculi (rare), foreign body, or condylomata (for diagnosis or removal)
- Urinary incontinence
  - Intrinsic sphincter deficiency (cystourethroscopy confirms the diagnosis and allows treatment with periurethral bulking agents)
  - Obstructive or irritative voiding symptoms (e.g., urgency, frequency, urge incontinence) unresponsive to conservative measures
- Suspected or known bladder diverticulum or fistula, or ectopic ureter (e.g., seen on radiograph)

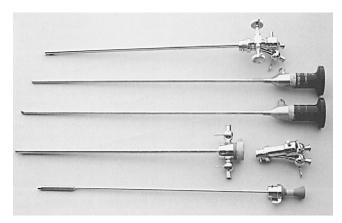

- Gross or microscopic hematuria
- Known or suspected urogynecologic malignancy
  - Staging or surveillance for bladder, cervical, or endometrial cancer
- Recurrent urinary tract infections
- Pelvic pain symptoms
  - Dyspareunia
  - Suspected interstitial cystitis, urethritis, or trigonitis (see also Chapter 12, Office Testing and Treatment Options for Interstitial Cystitis [Painful Bladder Syndrome])
  - Endometriosis of the bladder
- Traumatic injury to the lower genital tract
- Intraoperative assessment of the bladder or urethra
  - Exclusion of inadvertent intraluminal suture placement or bladder trauma after incontinence or prolapse correction procedures
  - Assessment of coaptation of the urethra after suburethral sling procedures
  - Evaluation of ureteral patency with intravenous indigo carmine dye

#### **CONTRAINDICATIONS**

- Acute cystitis, prostatitis, or pyelonephritis should be treated before cystourethroscopy is performed because sepsis has been reported after cystoscopy in an infected patient.
- Anticoagulated patient or patient with coagulopathy (either the anticoagulation/coagulopathy should be reversed or urology consulted).

#### **EQUIPMENT**

- Rigid cystoscope and sheath (Fig. 111-1).
  - Sterile rigid telescopes with 0-, 30-, 70-, and 120-degree lenses.
  - The 0-degree lens (forward looking) is useful for intraurethral work, the 30-degree lens (forward oblique) is useful for evaluation of the urethra and bladder, the 70-degree lens (lateral) is useful for inspecting the interior of the bladder, and the 120-degree lens (retrograde) is useful for retrograde viewing of the bladder neck.
  - Sterile sheath of 17- to 26-Fr diameter with inflow and outflow ports.
  - Sterile scope-to-sheath bridge. This bridge may have one or two operative ports that admit the passage of biopsy instruments or urethral catheters.
  - A light cable and light source compatible with the telescope.
  - Urethral dilators, including a range from 14 to 32 Fr.
- Flexible cystoscope and light source.
- Irrigation tubing.
- Distension medium in 500-mL to 3-L bags. Saline or Ringer's lactate may be used if electrocautery is not anticipated. If electrocautery is anticipated, then a nonconductive medium such as sterile water, mannitol, sorbitol, or glycine should be used, with

**Figure III-I** Cystoscope components, including (from top to bottom) operative sheath, telescopes (two), sheath and bridge, and obturator.

water having the advantages of increased visibility and, because it is hypotonic, lysing tumor cells.

- Cotton balls moistened with an antiseptic solution (e.g., povidone-iodine).
- Sterile gloves.
- Sterile cotton-tipped applicators.
- 1% or 2% lidocaine (Xylocaine) gel.
- Blue towel for tray top.
- Basin to capture irrigation runoff.

Although optional and expensive, video equipment, such as a camera, high-resolution monitor, video recorder, and printer, has its advantages. Video equipment provides a magnified, binocular view, allows the clinician the ability to maintain a more comfortable position when performing the procedure, is helpful for teaching or when an assistant is available, and provides the clinician greater eye protection from body fluids.

#### PREPROCEDURE PATIENT PREPARATION

Indications for, alternatives to, and risks of cystourethroscopy should be explained to the patient, and informed consent obtained before the procedure. The patient should be informed of the possibility of discomfort during and after the procedure, as well as the potential for postprocedure urinary tract infection.

If a urinary tract infection is suspected or the patient has a history of mitral valve prolapse, valvular heart disease or replacement, or a recent prosthesis such as a total knee or joint, a urine culture and sensitivity should be obtained and the patient placed on a broad-spectrum antibiotic for at least 3 days. If the patient is not allergic to fluoroquinolones, ciprofloxacin or levofloxacin is an appropriate choice (see Chapter 221, Antibiotic Prophylaxis).

#### **TECHNIQUE**

Before routinely performing cystoscopy, clinicians should familiarize themselves with the equipment and feel comfortable recognizing abnormalities or pathology on visualization of the urethra or bladder. Universal blood and body fluid precautions should be followed throughout the procedure.

#### **Preparation**

- 1. After the patient has emptied the bladder, *cleanse the urethral meatus* with an antiseptic solution.
- 2. Generously *lubricate the cotton-tipped applicator* with 1% or 2% lidocaine gel and insert it into the urethral meatus to the level of the bladder neck. Observe the angle of the urethra as an aid to inserting the cystoscope.

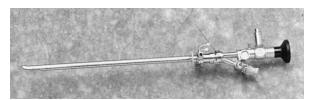

Figure 111-2 Assembled cystoscope with telescope, bridge, and sheath.

**NOTE:** Use sterile technique and wear sterile gloves from this point onward throughout the procedure.

#### Rigid Cystourethroscopy

- 3. Prepare the cystourethroscope as follows:
  - Assemble the cystourethroscope by attaching the 0-degree telescope to the bridge and sheath (Fig. 111-2).
  - Attach the light cable to the cystourethroscope and the light source. Turn on the light source before insertion to ensure proper illumination.
  - Attach the infusion tubing to the infusion port on the sheath, and attach this in turn to the appropriate instillation medium hung on a nearby intravenous pole. The tubing is then flushed.
- 4. Lubricate the distal portion of the cystoscope sheath with 1% or 2% lidocaine gel. Remove the applicator. After ensuring that all ports are in the closed position, start the flow of the infusion medium by opening the stopcock of the inflow port. The operator should have sole control of the fluid infusion through this port.

#### **Urethroscopy**

- 5. Insert the lighted and assembled cystoscope into the urethral meatus, following the line of the urethra. Initial insertion may be achieved using fluid as the obturator. Fluid is infused during inspection to a maximum of 350 to 500 mL or until the patient is uncomfortable. If resistance is encountered, the scope should not be forced; rather, the angle of insertion of the cystoscope should be reassessed. Continued difficulty in inserting the cystourethroscope may be an indication for urethral dilation before proceeding. Dilation can be performed serially using urethral dilators beginning with 14 Fr and dilating up to 32 Fr. Alternatively, a smaller-sized sheath can be used.
- Advance the cystoscope under direct visualization into the bladder lumen. Then withdraw it slowly until the internal urethral meatus is visualized. While slowly withdrawing the cystourethroscope, examine the entire length of the urethral mucosa for pathology (Fig. 111-3). Gentle palpation of the anterior vaginal

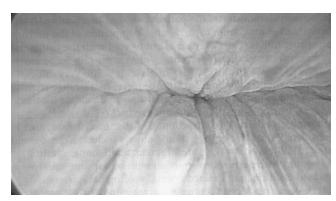

Figure 111-3 View of normal urethral mucosa.

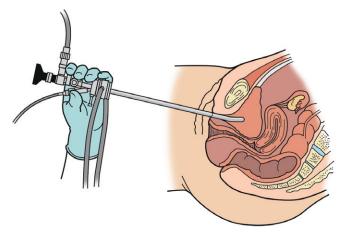

Figure III-4 Technique of cystoscopy using angled telescopic lens.

wall during withdrawal may help to identify a urethral diverticulum, which tend to occur on the posterior aspect of the urethra.

#### Cystoscopy

- 7. Remove the cystoscope and discontinue the infusion flow. Replace the 0-degree telescope with an angled-lens (30- or 70-degree) telescope and reinsert the reassembled cystoscope as described previously. For adequate cystoscopy the bladder should be filled to approximately 250 mL or greater. If the patient notes discomfort from overdistention of the bladder, open the outflow port on the sheath and drain an appropriate amount of fluid from the bladder.
- 8. Perform a systematic examination of the bladder lumen, apply suprapulsic pressure to facilitate visualization, and identify a small air bubble, which is usually present at the bladder dome. With this as a landmark, examine the anterior and lateral sidewalls in a stepwise fashion. To visualize the entire bladder dome, rotate the angled lens about the long axis of the telescope while keeping the camera in a fixed orientation (Fig. 111-4). Lateral torque, with the urethral meatus as the fulcrum, can cause pain and should be avoided. Intraluminal pathology, including the presence of tumor, endometriosis, trabeculations, stones, chronic cystitis, or hemorrhage, should be noted (Fig. 111-5). The bladder should be examined at various levels of filling; glomerulations and ecchymoses are frequently seen only with

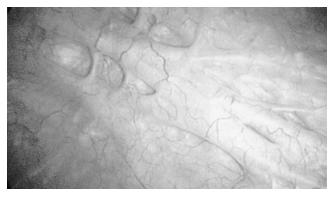

Figure 111-5 Cystoscopic evaluation of bladder lumen demonstrating coarse trabeculations (ridges).

- full distention. Intraluminal sutures inadvertently placed at the time of a previous urethropexy are generally identified on the lateral sidewalls at the 2 and 10 o'clock positions.
- 9. Visualize the trigone, located posteriorly just proximal to the internal urethral meatus at the 6 o'clock position. Any abnormalities should be noted. Rotating the scope 20 to 30 degrees to each side will allow visualization of the ureteral orifices. If one orifice is visualized, identification of the interureteric ridge will lead to the contralateral orifice. (In patients with large cystoceles, reduction of the prolapse may be necessary to see the orifices.) If possible, identify ureteral peristalsis with efflux of urine.
- Concurrent vaginal examination in women may be helpful for evaluating a cystocele. A concurrent rectal examination in men may be useful for assessing prostate size and length of the prostatic urethra.
- 11. For patients with pelvic pain or interstitial cystitis, bladder distention with at least 600 to 1000 mL may be therapeutic but usually requires general anesthesia because of poor tolerance in the office as a result of severe pain.
- 12. After completing the procedure, turn off the infusion of distention medium and drain the patient's bladder with the ancillary port on the cystoscope sheath. Samples of this drainage can be sent for cytologic analysis if desired (e.g., patient with prior history of malignancy). Remove the cystoscope and turn off the light source to prevent accidental injury from the hot light.
- Disassemble the cystoscopic telescopes, bridge, and sheaths and clean them by immersion in glutaraldehyde solution (Cidex) for 20 minutes before reuse.

#### Flexible Cystoscopy

- 14. Lubricate the distal portion of the cystoscope with 1% or 2% lidocaine gel.
- 15. Advance the cystoscope under direct visualization into the bladder lumen. (The flexible cystoscope is passed in a manner similar to a Foley catheter, except the lumen is visualized as it is passed.) Flex and torque the instrument to obtain a view of the same structures as visualized with rigid cystourethroscopy. The same maneuvers may be used as with rigid instruments to enhance visualization of various structures and pathology.
- 16. Withdraw the cystoscope slowly until the internal urethral meatus is visualized. While slowly withdrawing the cystoscope, examine the entire length of the urethral mucosa for pathology. The prostatic urethra will not be seen as clearly as with rigid instruments, but a general impression of prostatic size can be obtained.
- 17. Clean the flexible cystoscope and flush all channels and ports with soap and water. This should be followed by immersion in glutaraldehyde solution (Cidex) for 20 minutes before reuse.

#### **BIOPSY**

Bladder or urethral mucosa biopsy is useful for evaluation and histologic confirmation of suspect lesions, including possible interstitial cystitis or malignancy. Although it can be performed in the office, bladder biopsy usually requires a larger sheath to accommodate the biopsy forceps, is associated with patient discomfort, and occasionally requires electrocautery to control bleeding. Given these considerations, it is recommended that cystoscopic biopsies be performed in the ambulatory surgical suite. Flexible biopsy forceps are available for the rigid scopes and may be helpful for reaching areas of the bladder that are difficult to reach with rigid forceps such as the dome and anterior wall; however, rigid biopsy forceps can remove tissue samples up to 5 mm in diameter, whereas the size of fragments obtained with flexible biopsy forceps is usually less than 2 mm.

#### **COMPLICATIONS**

- Bacteriuria
- Sepsis
- Urethral or bladder neck trauma
- Bleeding
- Pain

Complications after cystourethroscopy are rare. The reported rate of bacteriuria after this procedure is 2% to 7%. Rare cases of systemic sepsis associated with performance of cystoscopy in the presence of untreated infection have been reported. Rarely, trauma to the urethra and bladder neck can result from instrumentation.

#### INTERPRETATION OF RESULTS

A complete review of abnormal findings at the time of cystoscopy is beyond the scope of this chapter. However, the clinician who routinely performs cystoscopy should be familiar with the normal appearance of the bladder and urethra. Abnormal anatomic findings should correlate with the patient's symptoms. In patients with overactive bladder symptoms (urgency, frequency, nocturia, enuresis, or urge incontinence), the urethra should be inspected for a stricture or diverticulum and the bladder inspected for trabeculations, infectious changes, and foreign bodies.

For the evaluation of incontinence, cystoscopy is useful in the evaluation of intrinsic sphincter deficiency (the internal urethral meatus is open at rest) and vesicovaginal and urethrovaginal fistulas. In patients with genitourinary pain syndromes, the urethra may appear atrophic and the bladder may reveal petechial hemorrhages, ecchymoses, glomerulations, or Hunner's ulcers consistent with interstitial cystitis (see also Chapter 112, Office Testing and Treatment Options for Interstitial Cystitis [Painful Bladder Syndrome]). Bladder distention, which is often therapeutic, can be accomplished at the time of cystoscopy with instillation of 600 to 1000 mL of solution.

Cystoscopy is useful for evaluation of lower urinary tract injury. Cystoscopy may reveal a bladder laceration or penetration of the bladder by sutures placed during surgery. To assess ureteral integrity and patency, patients can be given 5-mL intravenous indigo carmine at the time of cystoscopy. Both ureteral orifices should be noted to eject dye 5 to 10 minutes after intravenous injection. In some cases dye spillage may be delayed up to 15 minutes.

#### POSTPROCEDURE PATIENT EDUCATION

Each patient should be provided with instructions concerning expected postprocedure symptoms. A preprinted informational handout may be useful for this purpose. Specific information should include the following:

- 1. Patients should take antibiotic prophylaxis, if prescribed. They should be instructed to follow up immediately if dysuria, pyuria, or fever greater than 100.4° F develops within 72 hours of the procedure.
- A small amount of transient hematuria within the first few hours after cystoscopy is normal. If it persists or is excessive, the patient should be instructed to follow up immediately.
- 3. The patient may have some discomfort after the procedure. A short course of the bladder analgesic, phenazopyridine, may be used to alleviate this. If the discomfort persists, the patient should be instructed to follow up for evaluation.

#### **CPT/BILLING CODES**

- 52000 Cystourethroscopy (separate procedure)
- 52005 Cystourethroscopy, with ureteral catheterization
- 52204 Cystourethroscopy, with biopsy

- 52260 Cystourethroscopy, with dilation of bladder for interstitial cystitis; general or conduction (spinal) anesthesia
- 52281 Cystourethroscopy, with calibration and/or dilation of urethral stricture or stenosis
- 52285 Cystourethroscopy for treatment of the female urethral syndrome with any or all of the following: urethral meatotomy, urethral dilation, internal urethrotomy, lysis of urethrovaginal septal fibrosis, lateral incisions of the bladder neck, and fulguration of polyp(s) of urethra, bladder neck, and/or trigone

#### **ICD-9-CM DIAGNOSTIC CODES**

- 592.1 Calculus: ureteral
- 594.2 Calculus: urethral
- 595.1 Cystitis: interstitial
- 595.2 Cystitis: other chronic
- 596.2 Fistula: bladder, not elsewhere classified
- 597.80 Urethritis, unspecified
- 597.81 Urethral syndrome, NOS
- 598.0 Urethral stricture due to infection
- 599.1 Fistula: urethral
- 599.2 Diverticulum: urethral
- 599.7 Hematuria
- 625.6 Incontinence: stress
- 753.6 Bladder neck obstruction
- 788.1 Dysuria
- 788.20 Urinary retention, unspecified
- 788.21 Incomplete bladder emptying
- 788.30 Incontinence: unspecified
- 788.31 Incontinence: urge
- 788.33 Incontinence: mixed
- 788.37 Incontinence: continuous leakage
- 788.41 Urinary frequency
- 867.0 Injury: bladder/urethra, without mention of open wound

#### **ACKNOWLEDGMENT**

# OFFICE TESTING AND TREATMENT OPTIONS FOR INTERSTITIAL CYSTITIS (PAINFUL BLADDER SYNDROME)

Stephen A. Grochmal

Interstitial cystitis (IC), also known as painful bladder syndrome (PBS, which is actually a slightly broader category of disorders), is characterized by bladder pain of varying intensity, lasting over a prolonged period. IC is more prevalent in women but can also affect men, and the overall prevalence appears greater than was previously estimated. Identification, diagnosis, and treatment of IC are controversial, similar to other medical conditions of unknown etiology that are difficult to treat.

#### **ANATOMY**

The urinary and reproductive systems are related embryologically, and both systems develop from the intermediate mesoderm of the embryo. The endoderm that ultimately gives rise to the epithelium of the bladder trigone and urethra is the same as that which develops into the lower third of the vagina and vestibule. Therefore, conditions that affect the bladder throughout life may also produce a variety of vaginal or vulvar symptoms, and vice versa.

The superior surface of the bladder is covered with peritoneum that separates it from the coils of the ileum and the sigmoid colon. As the bladder fills (maximum capacity is about 500 mL), this superior surface bulges upward into the abdominal cavity and the covering peritoneum separates from the lower part of the anterior abdominal wall so that the bladder comes into direct contact with the anterior abdominal wall.

The glycosaminoglycan layer normally coats the urothelial bladder surface and renders it impermeable to any solutes. Defects in this layer may permit urinary irritants to penetrate the urothelium and activate the underlying nerve and muscle tissues. This process can lead to additional tissue damage, hypersensitivity, and pain. This ongoing bladder damage may also be propagated by mast cells in the bladder.

The pelvic floor and bladder are both innervated from sacral nerve roots S2, S3, and S4. These nerve roots include motor/efferent and sensory/afferent pathways of both the visceral and somatic systems.

Because of the proximity of the bladder to other surrounding structures, including the bowel, pelvic floor musculature, and reproductive organs, it is not surprising that if one of the pelvic organs becomes diseased, the other pelvic organ systems may exhibit similar symptoms. This should be kept in mind when evaluating pelvic pain of bladder origin.

#### **CLINICAL PRESENTATION**

Interstitial cystitis is defined by suprapubic pain related to bladder filling and is frequently accompanied by urinary frequency and urgency and nocturia in the absence of proven infection or other obvious pathologic process. Furthermore, the term *interstitial cystitis* is reserved for those patients with PBS symptoms who also have characteristic (but not pathognomonic) cystoscopic findings or histologic evidence during bladder hydrodistention.

Patients may also describe chronic pelvic pain (CPP) not due to their bladder pain, but associated with other ongoing symptoms or disorders such as dysmenorrhea, endometriosis, adenomyosis, vulvodynia, irritable bowel syndrome, and fibromyalgia.

Although the etiology of IC is clearly multifactorial, recent evidence suggests a strong correlation between IC and (1) dysfunctional, abnormal bladder epithelial permeability and (2) increased mast cell activity. The abnormal bladder epithelial permeability appears to be due to changes found in the bladder mucous layer. This layer contains defective glycosaminoglycans that increase the permeability of the urothelium to irritants, especially potassium. It is still unclear whether mast cells play a causative or secondary role in the disease.

IC is expressed as a continuum from mild to severe disease, and can persist for decades. The mild to moderate stages are often associated with symptom flares and remissions. Flares may occur in association with sexual intimacy or before menses, complicating the process of distinguishing IC from other gynecologic disorders. Subsequently, women often consult multiple clinicians (an average of five over a period of 4 or more years) before the correct and precise diagnosis is made; unfortunately, the causes of IC or any associated CPP cannot always be determined with a simple gynecologic examination.

Additional factors known to cause IC exacerbations include allergies, emotional or physical stress, exercise, sexual intercourse, remaining seated for prolonged periods (e.g., air travel), and ingestion of foods and drinks with a high potassium content (e.g., oranges, strawberries, coffee). Most patients in the early stages of IC complain of urgency and frequency; however, dysuria and dyspareunia can also be seen. The symptoms may vary from day to day but are usually gradual in onset and worsen over a period of months. Pain of increasing severity often becomes the predominant complaint.

IC or PBS symptoms can be associated with chronic pain and fatigue, a disturbance of the patient's home and work life, and a decreased overall quality of life. From a review of multiple surveys, up to 70% of patients claim sleep disturbance, more than 50% are unable to work full time, and almost 80% complain of dyspareunia leading to decreased sexual intimacy. More than 90% of patients surveyed claim that the symptoms of IC or PBS affect their daily activities.

#### **PATIENT INVESTIGATION AND DIAGNOSIS**

The work-up for IC should include a careful pelvic examination; during this examination, care should be taken to evaluate for tenderness of the anterior vaginal wall/bladder base. A urinalysis and urine culture should be obtained to rule out hematuria and infection. Conditions for which IC may be mistaken include recurrent urinary tract infection, overactive bladder, vulvar and vaginal conditions, and abdominopelvic adhesions. It is important to be aware of signs, symptoms, and risk factors for bladder cancer. Microscopic hematuria is the main sign, and, if present, cancer should be ruled out with a thorough urologic work-up, including cystoscopy (see Chapter 111, Diagnostic Cystourethroscopy). Risk factors for bladder cancer include age greater than 40 years, long-standing symptoms, and smoking.

Although additional procedures such as cystoscopy/cystoure-throscopy (with or without bladder hydrodistention) can be performed at the clinician's discretion, these procedures are not required for the diagnosis and treatment of IC or PBS. Bladder biopsy is not required except to rule out other disorders. Additional diagnostic tools such as biomarkers (e.g., antiproliferative factor) may play a future role in the diagnosis of IC or PBS, but further studies are needed. Urodynamic testing does not currently have a role in identification or diagnosis of IC or PBS.

## TOOLS FOR DIAGNOSING INTERSTITIAL CYSTITIS

The majority of patients with IC or PBS, even early disease, can be identified with the Pelvic Pain and Urgency and/or Frequency (PUF) questionnaire or the optional potassium sensitivity test (PST).

#### Pelvic Pain and Urgency and/or Frequency Questionnaire

When the clinical presentation and physical examination suggest IC, the PUF questionnaire (Fig. 112-1) is a rapid (<5 minutes), self-administered tool available to screen for IC. The PUF has been

PELVIC PAIN and URGENCY/FREQUENCY PATIENT SYMPTOM SCALE							
Please circle the answer that best describes how you feel for each question.							
	0	1	2	3	4	SYMPTOM SCORE	BOTHER SCORE
How many times do you go to the bathroom during the day?	3–6	7–10	11–14	15–19	20+		
2 a. How many times do you go to the bathroom at night?	0	1	2	3	4+		
b. If you get up at night to go to the bathroom does it bother you?	Never	Mildly	Moderate	Severe			
3 Are you currently sexually active? YES NO							
4 a. IF YOU ARE SEXUALLY ACTIVE, do you now have or have you ever had pain or symptoms during or after sexual intercourse?	Never	Occasionally	Usually	Always			
b. If you have pain, does it make you avoid sexual intercourse?	Never	Occasionally	Usually	Always			
5 Do you have pain associated with your bladder or in your pelvis (vagina, lower abdomen, urethra, perineum, testes, or scrotum)?	Never	Occasionally	Usually	Always			
6 Do you have urgency after going to the bathroom?	Never	Occasionally	Usually	Always			
7 a. If you have pain, is it usually		Mild	Moderate	Severe			
b. Does your pain bother you?	Never	Occasionally	Usually	Always			
8 a. If you have urgency, is it usually		Mild	Moderate	Severe			
b. Does your urgency bother you?	Never	Occasionally	Usually	Always			
SYMPTOM SCORE = (1, 2a, 4a, 5, 6, 7a, 8a)							
BOTHER SCORE = (2b, 4b, 7b, 8b)							
TOTAL SCORE = (Symptom Score + Bother Score)					)		

Figure 112-1 A score of 15 or greater is highly suggestive of interstitial cystitis. In some patients, especially adolescents, even a score in the range of 6 to 10 may warrant further investigation and treatment.

validated against the intravesical PST in both urologic patients suspected of having IC and gynecologic patients with pelvic pain. This questionnaire has proven to be of tremendous value for identifying patients with IC. Unlike other IC questionnaires, the PUF gives balanced attention to pelvic pain, urgency/frequency, and dyspareunia. (The cut-off score for a definitive IC/PBS diagnosis based on the PUF is 15 or higher; however, some patients have IC with a PUF score of 12 or higher. It is also the author's experience that in some patients with IC, particularly adolescent women not yet sexually active, the PUF score may be much lower than 12 because these patients fall out of the questionnaire's parameters.)

#### **Potassium Sensitivity Test**

The PST is an optional test that involves instilling potassium chloride solution into the bladder (Fig. 112-2). If the patient experiences urgency or pain, the presence of abnormal epithelial permeability is strongly suggested. During the PST, 40 mL of sterile water is instilled into the bladder and notation made of any associated pain. The bladder is then drained and filled with a 40-mL solution of 0.4 M potassium chloride (40 mEq KCl/100 mL water); a finding of increased pain during this second filling is considered indicative of bladder hypersensitivity and suggestive of IC or PBS. The PST can be an uncomfortable procedure; therefore, an intravesical "rescue" solution should be available to alleviate symptoms provoked by the test.

Some studies claim that the PST should not be used routinely because its results are nonspecific for IC or PBS. Although most patients with IC have a positive PST result, a small percentage will have a negative result, and the reason for this is unknown. More important, to minimize the use of the PST, one study found an 84% correlation with positive PST findings among individuals with PUF scores of 15 or higher. This has resulted in the PUF questionnaire gaining acceptance as a sensitive and easy-to-use surrogate for the PST.

Recently, investigators have reported that intravesical instillation of 2% lignocaine solution is useful for excluding patients with pelvic pain originating from organs other than the bladder (Taneja, 2010). Further studies are needed to substantiate this claim.

#### Indications

#### **Potassium Sensitivity Test**

- Validation of patient symptom scale (PUF questionnaire)/confirmation of bladder epithelial dysfunction
- Assessment or monitoring of current disease state/treatment
- Patient seeking second opinion concerning treatment of IC previously investigated by an unremarkable cystoscopy or hydrodistention
- Confirmation for "new to treat" clinicians of their clinical impression
- Validation for suffering patients that their disease is real

#### Intravesical Instillation Therapy

- Provide rapid relief as needed in patients suffering with bladder pain, symptoms, or flares
- "Jump start" therapy to complement initiation of oral treatment in newly diagnosed patients
- Adjunctive second-line therapy to multimodal oral treatment regimens
- In patients unable to tolerate oral treatment or when oral therapy is ineffective
- "At home" elective intravesical instillation treatments by patients

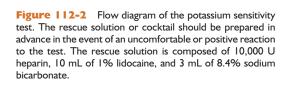

#### **Contraindications**

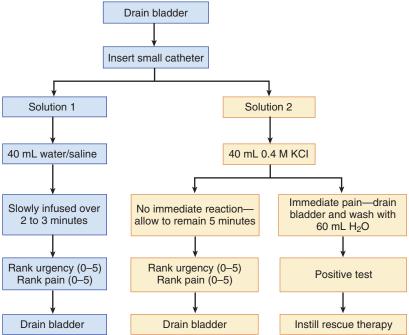

- Absolute: Known allergy or sensitivity to any of the components used in the test or instillation treatment solutions (e.g., lidocaine, heparin)
- Relative: Acute urinary tract infection

#### **Equipment and Supplies**

#### Potassium Sensitivity Test

- Examination table with or without pelvic tilt/stirrups
- Impermeable drapes
- Surgical prep solution (e.g., povidone-iodine, chlorhexidine)
- Gloves

- LoFric catheter (Astra Tech, Inc., Urology Division, Torrance, Calif; 8 to 10 Fr, 8 inches for female patients, 12 Fr for male
- Solution no. 1: 40 mL of sterile water or saline
- Solution no. 2: 40 mL of 0.4 M KCl (40 mEq of KCl/100 mL sterile water)
- One bottle of 100 mL sterile water for diluent
- Two 60-mL syringes
- 20-mL syringe
- 18-gauge needle
- Permeability Study Record Sheet (available online at www. expertconsult.com)

#### Rescue Solution\*

- 20-mL syringe
- Heparin sulfate, 10,000 U
- 10 mL lidocaine 1%
- 3 mL 8.4% NaOH (sodium bicarbonate)
- 100 mL sterile water for dilution.

NOTE: 100 to 200 mg of oral pentosan polysulfate sodium (PPS) emptied from its capsule, dissolved in 10 mL of buffered normal saline per 100-mg capsule, may be substituted for heparin.

#### Intravesical Instillation ("Jump Start" Therapy)

- LoFric catheter (8 to 10 Fr, 8 inches for female patients, 12 Fr for male patients)
- 20- or 30-mL syringe(s)
- 100 to 200 mg of oral PPS emptied from its capsule, dissolved in 10 mL of buffered normal saline per 100-mg capsule<sup>†</sup>
- 10 mL lidocaine 1% or 16 mL lidocaine 2%
- 3 mL 8.4% NaOH (sodium bicarbonate)
- Dimethyl sulfoxide (DMSO, is FDA approved for intravesical
- 100 mL sterile water for dilution

#### **Technique**

#### **Potassium Sensitivity Test**

- 1. The patient is awake and without anesthesia for this procedure.
- 2. Have the patient void completely.
- 3. Position patient in the dorsal position, preferably in stirrups. 4. Place an impermeable, waterproof drape under the patient's
- Cleanse/prepare the vulvar/urethral area as if you were inserting a Foley catheter. This is a clean, not sterile procedure.
- 6. Insert the straight catheter, drain any residual urine, and attach the syringe filled with solution no. 1 (see Fig. 112-2).
- Instill solution no. 1, wait, and record observations on Permeability Study Record Sheet (available online at www. expertconsult.com).
- 8. Drain the bladder.
- Attach the second syringe, instill solution no. 2 into subject's bladder, and wait 5 minutes.
- 10. Record patient's degree of provoked urgency and pain. Patients are rated on a scale of 0 to 5 (with 0 = no provocation and 5 = nosevere provocation). A score of 2 or more in the pain or urgency scale is considered a positive test. If the patient's bladder is abnormally permeable, the PST will provoke urinary urgency or pain well above the patient's baseline levels.
- 11. If necessary (e.g., if patient has an immediate reaction to solution no. 1 on instillation or after test is concluded and patient
- \*Prepare this solution in advance of performing the PST. Use sterile water to bring volume up to at least 20 mL.
- <sup>†</sup>Intravesical administration of PPS is an off-label use of the drug.

- voids), instill rescue solution immediately and have patient lie semiupright for approximately 10 to 20 minutes or until bladder discomfort dissipates.
- 12. Make a notation in the patient's records regarding the outcome of the test, any reaction, and administration of rescue solution, if used, and maintain a copy of Permeability Study Record Sheet

#### TREATMENT OPTIONS FOR INTERSTITIAL CYSTITIS OR PAINFUL BLADDER SYNDROME

Because of the multiple possible etiologies for IC or PBS, therapy should generally use a multimodal approach. The foundation of oral therapy for IC is PPS, 100 mg three times a day. Additional medications are added as needed. Currently, PPS is the only oral medication approved by the U.S. Food and Drug Administration (FDA) for the treatment of IC; it has been evaluated in five placebo-controlled trials. PPS is a compound that mimics the glycosaminoglycan layer on the surface of the bladder and is believed to help correct the dysfunctional bladder epithelium. Hydroxyzine (25 mg/day in the evening, 50 to 100 mg/day during allergy season) is prescribed to control histamine discharge associated with allergic flares, which can in turn provoke exacerbations of IC or PBS. Amitriptyline (25 mg/day at bedtime) can be added to block both peripheral and central neural activity. Occasionally, an anticholinergic is also used to control severe urinary urgency complaints. In many patients with IC or PBS, PPS must be administered for at least 3 to 6 months before its full effectiveness can be realized (Fig. 112-3).

If a more rapid treatment response is needed, intravesical "jump start" therapy can be initiated at the time of diagnosis. This consists of various therapeutic "cocktails" made from heparin, PPS, 8.4% sodium bicarbonate, lidocaine, or DMSO (Fig. 112-4). These cocktails are instilled directly into the bladder through a catheter to facilitate immediate relief, as opposed to the several weeks to months it may take for PPS alone to take effect. It should be noted that DMSO is the only FDA-approved medication for intravesical instillation. The current use of all other combinations of medications for intravesical therapy is considered off-label.

Evaluation of ongoing treatment can be accomplished with a repeat PUF questionnaire, looking for a change (decrease) in score as treatment progresses. Another form that may be useful is the Patient Overall Rating of Improvement of Symptoms (PORIS). The PORIS helps in assessing patient progress with long-term treatment regimens. This form should be maintained as part of the patient record (available online at www.expertconsult.com).

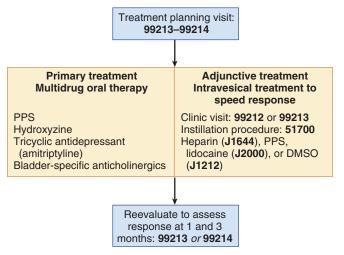

Figure 112-3 Synopsis of treatment options with appropriate codes. DMSO, dimethyl sulfoxide; PPS, pentosan polysulfate sodium.

**Figure 112-4** Example of components used for intravesical instillation, including 8-Fr catheter and open capsule of pentosan polysulfate sodium.

Surgical intervention is rarely indicated or beneficial. In addition to pharmacologic therapy, various supportive or behavioral measures may be helpful. Effective self-care options for patients with IC or PBS include stress reduction and comfort activities such as pet therapy, meditation, and even prayer. Improvement in IC symptoms has been reported using self-hypnosis and posthypnotic suggestion in patients refractory to conventional medical treatments.

#### Technique for Intravesical Instillation Therapy

- 1. Prepare the therapeutic cocktail solution in a single syringe.
- 2. Follow steps 1 through 5 as described in PST Technique section.
- 3. Place catheter into bladder (10 Fr, 8 inches for female patients, 12 Fr for male patients).
- 4. Drain the bladder.
- 5. Attach the syringe and instill the therapeutic solution.
- 6. Have the patient retain the instilled solution for 10 to 20 minutes.
- 7. Remove the catheter.
- 8. Direct the patient to void the solution.
- 9. Make a notation in the patient's record of the solution used, amount, and the patient's tolerance for the procedure.

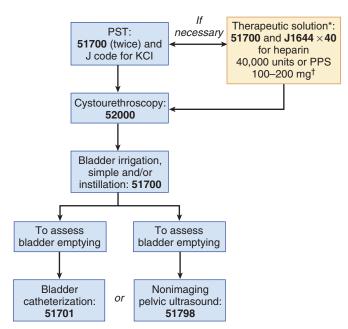

Assuming that the bladder is the source of pain in the patient with IC, direct treatment of the bladder surface with a therapeutic solution may result in immediate and profound relief and improvement of symptoms. This symptom improvement resulting from the instillation therapy may aid in differentiating bladder-based pain from other forms of pelvic discomfort. Some clinicians use a purely anesthetic cocktail, such as lignocaine or bupivacaine with 2% lidocaine jelly, for this purpose.

#### **COMMON ERRORS**

- Mix-up between solutions nos. 1 and 2 during the PST (label each syringe after preparation and before use).
- Incorrect quantities of components for cocktail solutions (record components as you prepare the solution).
- Failure to record the patient reactions during the PST (keep record sheet handy during the PST).
- Failure to have the rescue solution available at the start of the PST (should be prepared along with testing solutions).
- Failure to observe the patient at least 15 minutes post-PST voiding for any delayed response of pain or discomfort requiring you to administer the rescue solution.

#### **COMPLICATIONS**

 Rarely, an expected adverse effect may include a worsening of symptoms when the effects of the rescue solution or therapeutic solution have ceased. Reassure the patient that this exacerbation will dissipate within a few hours.

**Figure 112-5** Listed CPT and J codes for the PST, catheterization, and cystourethroscopy procedures performed in-office. KCl, potassium chloride; PPS, pentosan polysulfate sodium; PST, potassium sensitivity test. \*Solution also includes 10 mL of 1% lidocaine or 16 mL of 2% lidocaine and 3 mL of 8.4% sodium bicarbonate (not billable). †PPS 100 to 200 mg (not billable) may be substituted for heparin. Intravesical instillation of PPS is an off-label use of this product.

 Rarely, urinary retention. Treat as needed with catheterization to relieve discomfort.

#### **CPT/BILLING CODES**

For all newly diagnosed patients with IC there are specific codes for these procedures listed on the flow chart in Figure 112-5.

#### **Laboratory Testing**

# SUPRAPUBIC CATHETER INSERTION AND/OR CHANGE

Robert E. James • James R. Palleschi

Suprapubic catheters are normally used to provide short-term urinary drainage. If the patient's age or comorbid conditions preclude corrective surgery, the temporary catheter may be left in place or, with the aid of an exchange wire and appropriate dilators, may be replaced with a permanent suprapubic catheter.

#### **INDICATIONS**

- An impassable urethral stricture, bladder neck contracture, or obstruction
- Inability to pass a urethral catheter over an elevated bladder neck or an enlarged median lobe of the prostate gland
- Urethral trauma
- Recent urethral or bladder neck reconstructive surgery
- Inability to tolerate a urethral catheter and unwilling or unable to perform intermittent self-catheterization
- Bladder drainage required in the presence of a significant urethral or prostate infection
- Severe phimosis precluding the insertion of a urethral catheter (see Chapter 119, Dorsal Slit for Phimosis)

#### **CONTRAINDICATIONS**

- Uncooperative patient
- Anticoagulated patient or patient with coagulopathy (either the anticoagulation/coagulopathy should be reversed or urology consulted)
- Cellulitis over the insertion site
- Surgical scar in suprapubic area, or bladder or pelvic anatomic abnormality from previous surgery, cancer, or trauma (small bowel may be interposed in the retropubic space; however, ultrasonographic guidance may be helpful for avoiding small bowel; see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography])

#### **EQUIPMENT**

- Local anesthetic: 10-mL lidocaine 1% to 2%
- 10-mL syringe; 1½-inch, 22-gauge spinal needle
- Antiseptic skin preparation (e.g., povidone–iodine)
- Sterile towels
- Sterile saline, to possibly fill the bladder, irrigate the catheter, or inflate a Foley bulb
- Mask and sterile gloves
- Mounted scalpel blade (no. 11 or no. 15)
- Suture scissors, needle holder, and 2-0 nylon suture
- Closed urinary drainage system
- Suprapubic catheter set

**NOTE:** There are many manufacturers of suprapubic catheters and insertion kits, including the Bonnano catheter (Becton-Dickinson Corp.), Stamey percutaneous suprapubic catheter set (Cook Medical/Urological), and the Simplastic suprapubic catheter/ SupraFoley suprapubic catheter introducer (Rusch, Inc./Teleflex Medical).

The principal components of each set, except for the SupraFoley suprapubic catheter introducer, are a metal obturator and the suprapubic catheter. The metal obturator is placed down through the suprapubic catheter and is subsequently removed when the catheter is appropriately positioned within the bladder. The end of the catheter may consist of a *coudé tip* (*with balloon*), *Malecot tip*, or *Foley*. Unlike the red rubber catheter (also known as the *Robinson*), which is not self-retaining, all of these catheters are equally effective in retaining themselves within the bladder (Fig. 113-1).

#### PREPROCEDURE PATIENT PREPARATION

Explain the indications for, alternatives to, and risks of the procedure to the patient. Informed consent should be obtained. The patient should know what to expect during the procedure, including the need for injection of local anesthetic before the procedure. Also explain to the patient that mild to moderate suprapulic discomfort may be experienced for a few hours to days after this procedure.

#### **TECHNIQUE**

- 1. Place the patient in the supine position. If the bladder is not palpable, either the procedure should be delayed until the bladder can be easily identified or else the insertion should be completed with ultrasonographic guidance (see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]).
  - **NOTE:** If the patient has a bladder or pelvic anatomic abnormality from previous surgery, cancer, or trauma, the procedure should be performed only with the aid of ultrasonographic guidance.
- 2. Maintain sterile technique and observe universal blood and body fluid precautions. Prepare the suprapubic skin with an antiseptic solution and drape with sterile towels. Inject the local anesthetic into the skin overlying the abdominal wall, into the subcutaneous layer, into the fascia, and down to the dome of the bladder. After penetrating the subcutaneous layer, aspirate before injection to avoid intravascular injection.
- 3. With the scalpel, make a 1-cm horizontal skin incision (some clinicians also incise the anterior rectus fascia) 5 cm above the symphysis pubis in the midline (in both adult and pediatric patients). At this point, some clinicians prefer to pass a 22-gauge

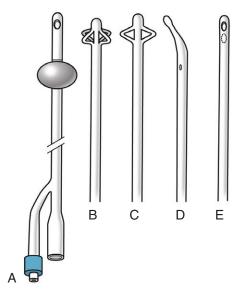

Figure 113-1 Commonly used catheters. A, Foley-type balloon catheter. B, Malecot self-containing, four-wing urethral catheter. C, Malecot self-retaining, two-wing catheter. D, Coudé hollow, olive-tip catheter. E, Robinson urethral catheter. (From Walsh PC, Retik AB, Vaughan ED Jr, Wein AJ [eds]: Campbell's Urology, 7th ed. Philadelphia, WB Saunders, 1998.)

spinal needle down and into the bladder. This will verify the bladder location before the suprapubic catheter is inserted. If the bladder is distended, this procedure is not necessary. If the bladder is not distended sufficiently to guide the obturator, the long needle can also be used to fill the bladder with sterile saline solution. Alternatively, ultrasonography can be used to determine if the bladder is full and for guidance.

- 4. Once the incision has been made, place the metal obturator into the lumen of the suprapubic catheter, with the sharp oblique end of the obturator extending beyond the tip of the catheter (Fig. 113-2). Advance the obturator and catheter together through the incision at a 60-degree caudal angle toward the bladder neck (approximately the mid-perineal area; Fig. 113-3). With momentary pressure, advance the catheter through the rectus sheath and muscle and into the dome of the bladder. This requires inserting it a total of approximately 5 cm below the skin in adults.
- 5. Advance the catheter and obturator an additional 5 cm in adults to ensure appropriate positioning. Remove the obturator; urine will be seen passing from the suprapubic catheter. After the obturator is removed, the wings of the Malecot type of catheter (Stamey suprapubic catheter) will expand, or the pigtail tip of the Bonnano catheter will coil inside the bladder to prevent it from falling out. If the catheter has a balloon tip, once it has been appropriately positioned within the bladder, inflate the balloon with sterile saline.

Alternatively, the SupraFoley suprapubic catheter introducer consists of a plastic sheath, through which a sharp, plastic obturator is inserted. Advance the obturator through the incision and the rectus sheath, into the bladder. Then remove the obturator and advance a Foley catheter down through the plastic sheath into the bladder. The balloon is filled with 5 to 10 mL of water or saline. A tab is located on the top edge of the plastic sheath; pull down and remove it. This removes a strip of the sheath,

Figure 113-2 Suprapubic catheter with obturator in place.

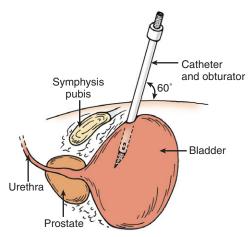

Figure 113-3 Insertion and advancement of the catheter and obturator.

allowing the removal of the sheath and leaving the catheter in place in the bladder.

- Pull back the catheter until the wings, coil, or balloon is resting against the dome of the bladder.
- 7. Secure the catheter in place with a nylon suture.
- 8. Using sterile saline, irrigate the catheter to ensure appropriate drainage and position.
- Connect a drainage bag to the catheter, using an overnight or bedside drainage bag, leg bag, or abdominal drainage system (belly bag).

#### **COMPLICATIONS**

- Perivesicular bleeding
- Gross hematuria
- Failure to drain
- Infection
- Intestinal perforation (more likely when the bladder is not distended, when the normal anatomy is distorted by previous surgery, cancer, irradiation, or trauma, or when the obturator and catheter are not introduced at the correct angle; normally, a small perforation will seal spontaneously without consequence)

#### SUPRAPUBIC CATHETER REPLACEMENT

Usually, a suprapubic catheter is replaced every 6 weeks, or whenever it is not draining properly. If the catheter has been in place for several weeks and a mature tract is established, the existing catheter may be removed and replaced with a similar catheter. First, place an obturator in the new catheter. Next, fill the bladder with sterile saline or water, and remove the catheter. The sterile water or saline will begin to pass through the suprapubic catheter site, and, consequently, the catheter needs to be replaced promptly. Advance the new catheter with obturator down the tract until the sterile water or saline begins to exit through or around the catheter. Usually a local anesthetic is not required.

If the catheter needs to be replaced before the tract is mature, the bladder should be filled with sterile saline or water before removing the catheter. If the catheter is obstructed, it should be removed and another catheter inserted once a distended bladder can be palpated. At that time, a new catheter may be inserted in the same tract, using the technique described previously. Ultrasonographic guidance should be used if the bladder cannot be positively identified or palpated.

With a Malecot or winged-tip catheter, frequently the wings are soft enough that they will retract as the catheter is removed. If there is difficulty removing the catheter, insert the obturator in the catheter to straighten the wings before removing the catheter. The tension in the pigtail is maintained by a silk suture that runs through the catheter and exits near its end. There it is tied around a small post. When the suture is cut or released, the pigtail will uncurl and can be removed.

If an open suprapubic cystotomy has been performed, a mature tract between the skin and the bladder usually is formed within 4 to 6 weeks. If the catheter must be replaced, select a similar-sized catheter. Normally, a catheter guide or obturator is not required. The new catheter should be introduced into the bladder immediately after removing the original one. After inflating the balloon with 5 to 10 mL of sterile saline, irrigate the bladder to ensure that the catheter is draining properly.

After catheter replacement, connect an overnight or bedside drainage bag, leg bag, or abdominal drainage system (belly bag).

#### **USE OF ANTIBIOTICS**

For suprapubic catheter placement, if a urinary tract infection is suspected or the patient has a history of mitral valve prolapse, valvular heart disease or replacement, or a recent prosthesis such as a total knee or joint, a urine culture and sensitivity should be obtained and the patient placed on a broad-spectrum antibiotic for at least 3 days. If the patient is not allergic to fluoroquinolones, ciprofloxacin or levofloxacin is an appropriate choice.

Prophylactic antibiotic therapy is not required when changing a suprapubic catheter. If a clinically significant urinary tract infection is suspected, a specimen of urine should be obtained for a culture and sensitivity and an oral antibiotic ordered until the culture results are available. Appropriate choices, depending on the patient's allergy history, include nitrofurantoin or a fluoroquinolone.

#### POSTPROCEDURE PATIENT EDUCATION

Explain again to the patient that mild to moderate suprapubic discomfort may be experienced for a few hours to days after this procedure. As long as the catheter is in place, intermittent hematuria and irritating voiding symptoms may be present. The patient should know to take good care of the catheter system, to keep it clean and dry, and to not let the bag drag on the floor. Review additional catheter care, including the use of an overnight or bedside drainage bag, leg bag, or abdominal drainage system (belly bag). Once a day, the patient should wash his or her hands with soap and water and then use a clean, soapy washcloth to clean the catheter and the skin around it. Hydrogen peroxide should be useful for removing any crustiness that does not come off with soap and water. After washing with soap or peroxide, the catheter should be rinsed with clean water and patted dry. The patient should take care not to pull too much on the catheter. If the patient wants it, a slit gauze can be placed over the catheter. Tell the patient to contact the clinician if increasing pain, excessive bleeding, temperature greater than 101° F, or a nonfunctioning catheter is noticed.

After the catheter is removed, patients should be aware that they will have lost some of the ability to sense a full bladder; therefore, they should urinate every 2 hours for 1 to 2 weeks, even after going to bed. They should drink plenty of fluids, but not force them, and they should refrain from fluids for 2 hours before going to bed. Patients should expect the site to drain small amounts of urine for

a few days, so they should keep it covered with gauze. They should clean the site with soap and water at least once a day.

## SUPRAPUBIC TAP OR ASPIRATION

Robert E. James • James R. Palleschi

Suprapubic aspiration is a valuable diagnostic procedure, and, occasionally, it may even be a valuable therapeutic tool. In most cases, suprapubic aspiration can be performed safely at the bedside or in the clinician's office. (For insertion of suprapubic catheters, see Chapter 113, Suprapubic Catheter Insertion and/or Change.)

To review the anatomy, clinicians should be aware that the dome of the bladder has peritoneal attachments and that needle penetration into this area can cause injury to bowel or an intraperitoneal bladder perforation. The colon lies posterior and inferior to the bladder, so the clinician should avoid advancing the needle through both walls of the bladder. Alongside the bladder, in the pelvis, lie significant vascular structures, including the common iliac and hypogastric vessels. Aspiration in this area may lead to inadvertent and significant hemorrhage.

A properly directed needle will penetrate only the skin and subcutaneous tissue of the lower anterior abdominal wall, the rectus sheath, the peritoneum, and the anterior bladder wall.

#### **INDICATIONS**

- Collection of a urine specimen for analysis, culture, and sensitivity using sterile technique
- Temporary relief of acute urinary retention in patient not able to be catheterized

#### **CONTRAINDICATIONS**

- Anticoagulated patient or patient with coagulopathy (either the anticoagulation/coagulopathy should be reversed or urology consulted)
- An uncooperative patient (see Chapter 2, Procedural Sedation and Analgesia)
- Infection or cellulitis of the suprapubic area
- Full bladder not palpable\*
- Patient not able to lay supine or have his or her bladder palpated\*
- Surgical scar in suprapubic area, or bladder or pelvic anatomic abnormality from previous surgery, cancer, or trauma (small bowel may be interposed in the retropubic space)\*
- Abnormalities of genitourinary anatomy, enlargement of pelvic organs (e.g., ovarian cysts, uterine fibroids), distention or enlargement of abdominal viscera (including intestinal obstruction)\*

#### **EQUIPMENT**

- Local anesthetic: 10 mL lidocaine 1%
- Needles:
  - For anesthetic: 11/2-inch, 25- to 30-gauge needle
  - Localization needle: 4-inch, 22-gauge spinal needle
- \*Ultrasonographic guidance may allow suprapubic aspiration to be performed in these situations and may be helpful for avoiding complications (see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]).

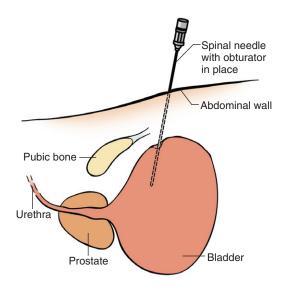

- Aspiration needle: In most cases, the localization needle will be sufficiently large to obtain an adequate urine specimen. If not, an 18- or 20-gauge intravenous needle may be used.
- 10-mL syringe
- Microscope slide for direct examination, methylene blue, and Gram's stain
- Sterile urine culture collection container

#### PREPROCEDURE PATIENT PREPARATION

Review the purpose of the procedure, risks, alternatives, and the technique with the patient and family. The patient may experience some pain in the suprapubic area with injection of the local anesthetic and during the procedure. He or she may also experience some hematuria for 24 to 48 hours after this procedure. Obtain informed consent.

#### **TECHNIQUE**

- 1. Place the patient in the supine position on the examination table. Examine the suprapubic area by palpation and percussion to identify the distended bladder. If the distended bladder cannot be identified positively, the procedure should be delayed until the bladder can be identified, or the procedure may be performed with ultrasonographic guidance.
- Cleanse the suprapubic area with an antiseptic solution and drape in a sterile fashion. Maintain the sterile technique and observe universal blood and body fluid precautions.
- 3. In the midline, anesthetize the skin approximately 2 inches above the symphysis pubis (in both the adult and the pediatric patient). Next, inject sequentially down to the fascia and bladder, aspirating each time before injection. In the adult, usually 10 mL is required to anesthetize the skin, abdominal wall, and abdominal bladder. In a child, the same can be accomplished with 3 to 5 mL of anesthetic.
- 4. Direct the 22-gauge spinal needle caudad toward the bladder neck, with the obturator in place (Fig. 114-1), through the anesthetized skin at a 60-degree angle to the skin. If the bladder is distended, the needle will enter the abdominal bladder after it has been advanced approximately 2 inches in the adult.
- 5. Remove the obturator and connect a sterile syringe (Fig. 114-2) to aspirate urine from the bladder. If urine is not obtained, slowly advance the needle, applying continuous suction on the syringe. If the specimen cannot be obtained after advancing the needle an additional 2 inches, terminate the procedure and start again, as described previously, but direct the needle at a 50-degree angle to the skin. If you are unsuccessful a second time, the procedure should be delayed until the bladder is further distended, or the procedure should be performed with ultrasonographic guidance. If continued difficulties are encountered, a urology consultation should be obtained.

Midsagittal view

Figure 114-1 Insertion of the spinal needle with the obturator in place.

#### **COMPLICATIONS**

- Transient hematuria
- Perivesicular hematoma
- Intestinal perforation (if this occurs with a 22-gauge needle, it should seal spontaneously and not be a problem)

#### POSTPROCEDURE PATIENT EDUCATION

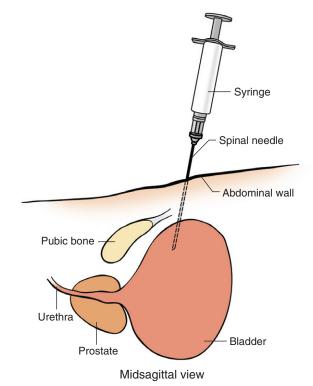

The patient may have some discomfort or soreness in the area for a day or so, which should be relieved by acetaminophen or a nonsteroidal anti-inflammatory drug. The patient should notify the clinician in case of persistent (lasting longer than 2 days) or increasing blood in the urine, increasing abdominal pain, difficulty urinating, or a temperature above 101° F.

## BEDSIDE URODYNAMIC STUDIES

Jeffrey R. Dell

The diagnosis and management of urinary incontinence and voiding dysfunction (e.g., frequency, dysuria, retention) are often challenging. Urinary incontinence has many etiologies, but it is most often the result of urethral incompetence (genuine stress incontinence), detrusor instability (urge incontinence), a combination of both (mixed incontinence), or poor bladder emptying (overflow incontinence). Urodynamic testing, specifically the cystometrogram, is used to demonstrate and differentiate among these conditions. Establishing the correct diagnosis is critical for developing an effective management plan. Although the patient history and physical examination may provide preliminary data regarding the underlying cause of incontinence or other urinary tract dysfunction, urodynamic testing provides an objective assessment while increasing the sensitivity and specificity of the diagnostic work-up.

Urodynamics is the study of the hydrodynamics and muscle activity of the lower urinary tract, with cystometry and uroflowmetry being the mainstays. Cystometry assesses the filling–storage phase by measuring the pressure–volume relationship of the bladder as it distends and contracts. It helps diagnose abnormalities of detrusor activity, sensation, capacity, and compliance. In contrast, uroflowmetry evaluates the voiding phase by measuring the urine volume voided over time. The combination of cystometry and uroflowmetry allows detection of both anatomic (obstructive) and physiologic (functional) voiding abnormalities.

Studies have shown that bedside (simple) urodynamic testing has a sensitivity of *up* to 75% for the correct diagnosis in the evaluation of urinary incontinence. It is easy to perform and cost effective in the office setting, and is frequently performed by the office personnel. A correlation of these test results with the patient history and physical examination usually determines the cause of urinary incontinence or other voiding dysfunction. Most conservative management protocols can be initiated on the basis of these results alone, without the need for formal multichannel urodynamic studies (see Chapter 116, Urodynamic Testing [Multichannel]).

However, in certain patients, greater sensitivity or specificity or more precise measurements may be needed. Examples include patients with diabetes; individuals with neurologic disorders; and patients needing surgery for incontinence, especially if they are at high surgical risk. Male patients also frequently require multichannel urodynamic testing. Additional examples include following pelvic radiation or surgery or for patients with incontinence and a confusing diagnosis or mixed etiology. Incontinence after failed surgery for incontinence or failing routine treatment or where the treatment progress needs to be monitored quantitatively may require more precise measurements. For all of these situations, formal uroflowmetry or formal cystometry is indicated, each being a part of formal multichannel urodynamic testing.

#### **INDICATIONS**

- Urinary incontinence
- Overactive bladder symptoms (urgency, frequency, nocturia, enuresis)

- Urinary retention or incomplete bladder emptying (ultrasonography can also be used to determine postvoid residuals; see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography])
- Pelvic pain
- Painful voiding syndromes

#### **CONTRAINDICATIONS**

- Active cystitis
- Recurrent cystitis or gross hematuria (after cystoscopy and imaging have ruled out malignancy and stones, bedside urodynamics may be helpful)
- Intolerance of urethral catheterization
- Uncooperative patient
- Formal, multichannel urodynamic testing indicated (see Chapter 116, Urodynamic Testing [Multichannel])

Patients with active cystitis, recurrent cystitis, or gross hematuria should be evaluated and treated before urodynamic testing. Patients unable to tolerate urethral catheterization in the office or who are uncooperative are not candidates for bedside urodynamic testing.

#### **EQUIPMENT**

See Figure 115-1.

- Nonsterile gloves
- Stopwatch
- Graduated voiding container
- Iodine swabs
- Water-based lubricating gel (nonanesthetic)
- 14-Fr red rubber urinary catheter
- Sterile urine specimen container
- Urinalysis Chemstrips
- 50-mL catheter-tip syringe with bulb or plunger removed
- 500 mL of room-temperature sterile saline or sterile water
- Sterile cotton-tipped swab with anesthetic gel

#### PREPROCEDURE PATIENT PREPARATION

All patients should be counseled regarding the indications, techniques, alternatives, and complications associated with urethral catheterization and bedside urodynamics. Clear communication and instructions should improve patient comfort during testing and thereby improve the results obtained. Patients should be instructed to come to the office with a full bladder to maximize information obtained from initial uroflowmetry. Each step of the procedure should be explained to the patient before proceeding.

#### **TECHNIQUE**

Clinicians should follow universal blood and body fluid precautions when performing this procedure.

Figure 115-1 Equipment used for urodynamic testing.

#### Simple Uroflowmetry

- 1. The patient's bladder should be very full. If not, provide fluids and time for the patient to fill the bladder. Because urine flow parameters depend on the volume voided, the patient needs to be able to void at least 200 mL for this test to be reliable.
- 2. In a relaxed, private setting, tell the patient to void into a graduated container in hand or placed over the commode. The total time to void is recorded with the stopwatch, the total volume voided measured, and both are documented.

#### **Simple Cystometry**

- 3. After the patient has voided, clean the external urethral meatus with iodine swabs and insert the lubricated tip of the urinary catheter into the bladder lumen. Drain the residual urine into the sterile specimen container and record the postvoid residual volume. After completion of the cystometry and cough stress test, perform a urinalysis on this specimen to rule out urinary tract infection. In patients with a positive urinalysis, send the specimen for urine culture.
- 4. With the urinary catheter in place, attach the 50-mL syringe (with bulb or plunger removed) to the proximal end of the urinary catheter and hold it approximately 15 cm above the pubic symphysis. Fill the bladder by slowly pouring the sterile saline or sterile water through the open-top syringe in increments of 50 mL (Fig. 115-2). Take care to keep the tip of the catheter within the bladder lumen (i.e., avoid withdrawing it into the urethra).
- 5. During filling, ask the patient to report when he or she feels the first sensation of fullness and then the first urge to void, as well as when he or she has reached maximum bladder capacity. Record the total volume infused for each of these sensations.
- 6. Observe the water level in the syringe during filling; it should fall steadily. A sudden rise in the water level with or without associated urgency or incontinence may indicate an uninhibited detrusor contraction or detrusor instability (Fig. 115-3). Other causes of a "water hiccup" may be artifact (e.g., Valsalva maneuver, cough by the patient) or the catheter tip slipping into the proximal urethra.

#### Cough and Valsalva Stress Tests

7. After the bladder is filled to maximum capacity, remove the catheter and examine the patient in the supine dorsolithotomy position. The patient is asked to cough or perform a Valsalva maneuver, and the external urethral meatus is observed for signs of urine leakage. Abrupt urine leakage with a cough suggests stress urinary incontinence, whereas prolonged leakage after ces-

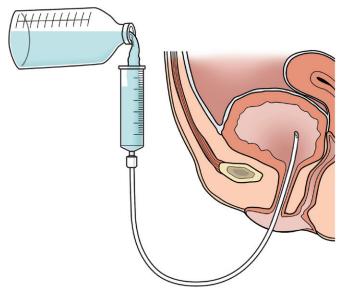

Figure 115-2 Cystometry.

sation of the cough indicates cough-induced *detrusor instability*. In women, if urinary leakage is observed in the vagina from the anterior vaginal wall, a *vesicovaginal fistula* should be considered.

8. Repeat the test with the patient standing.

#### Cotton Swab Test (Q-Tip Test) for Women

9. After the supine and standing cough stress test, place the patient in the supine dorsolithotomy position and reexamine her. Insert a cotton-tipped swab with anesthetic gel into the urethra until resistance is overcome; this indicates its position at the bladder neck. Record the swab resting angle relative to the horizontal plane. Ask the patient to cough or perform a Valsalva maneuver again, and measure the maximum angle of

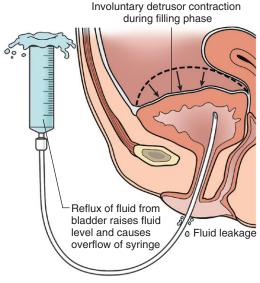

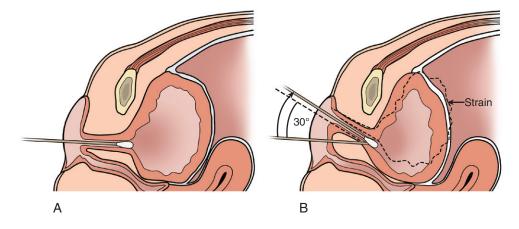

Figure 115-3 Involuntary detrusor contraction.

**Figure 115-4** Cotton swab test for ureterovesical junction mobility. **A,** Cotton swab at rest. **B,** Cotton swab with strain (Valsalva).

deflection. The difference between this value and the resting angle is the *angle of change*. An angle of change of greater than 30 degrees indicates *urethral hypermobility* (Fig. 115-4).

#### Measurement of Postvoid Residual

- Next, instruct the patient to void into the graduated container. Measure and record the amount voided (total void).
- Determine a second postvoid residual by subtracting the measured total void from the maximum bladder capacity noted on filling cystometry.

#### **COMPLICATIONS**

- Urinary tract infection (rare)
- Transient gross hematuria
- Urethral discomfort, transient
- Pelvic pain, transient

Bedside urodynamics are associated with few complications. In rare cases, patients may develop a urinary tract infection after the procedure. These patients should be treated accordingly. Routine prophylactic antibiotics after the procedure are not usually indicated.

Transient gross hematuria may be noted after the procedure, especially after a difficult catheterization in a postmenopausal woman with urethral atrophy. This usually resolves spontaneously within 48 hours. Some patients may complain of urethral discomfort or pelvic pain after testing. These symptoms are usually self-limited, but these patients may benefit from a short course of phenazopyridine (Pyridium). Cystoscopy-urethroscopy should be considered in patients with hematuria or lower urinary tract pain that persists beyond 48 to 72 hours (see Chapter 111, Diagnostic Cystourethroscopy).

#### INTERPRETATIONS OF RESULTS

Uroflowmetry with measurement of a postvoid residual assesses bladder emptying and evaluates for overflow incontinence. Most experts consider uroflowmetry to be normal if the patient *voids at least 200 mL in the course of 15 to 20 seconds*. More specific normal flow rates have been determined by age and sex (Abrams and Torrens, 1979). For men younger than 40 years, between 40 and 60 years, and older than 60 years of age, normal rates are 22 mL/sec, 18 mL/sec, and 13 mL/sec, respectively. In women younger than 50 years of age, the flow rate be should be greater than 25 mL/sec; for women older than 50 years of age, it should be greater than 18 mL/sec. The normal flow pattern (volume over time) is bell-shaped and continuous. Prolonged voiding times may indicate an obstructed

voiding pattern resulting from increased outlet resistance (e.g., ure-thral obstruction, external sphincter dyssynergia) or poor propulsive force (detrusor dysfunction). An interrupted pattern suggests straining to void or lack of coordination between detrusor muscle contraction and sphincter relaxation.

Cystometry evaluates bladder function, including sensation, compliance, and detrusor activity during filling. Most patients experience a first sensation of filling at 100 to 150 mL, first urge to void at 200 to 350 mL, and maximum bladder capacity at 400 to 550 mL. Urge incontinence should be considered in patients with reduced bladder capacity, with or without a spontaneous detrusor contraction and coexisting overactive bladder symptoms. Patients with increased bladder capacity should be evaluated for a neurogenic bladder. Urge incontinence from detrusor instability is documented when an involuntary contraction results in an overflow of the filling syringe (see Fig. 115-3). A cystometrogram is the best method for differentiating between bladder outlet obstruction and poor detrusor muscle contractility.

Normal values for a postvoid residual are not universally established, but various experts have defined a normal postvoid residual measurement as less than 200 mL and less than 20% of the total void. Patients with urinary frequency or incontinence and a normal postvoid residual have a bladder storage problem, and this can result from disorders of bladder compliance, involuntary bladder contractions, bladder hypersensitivity, or bladder outlet abnormalities. Bladder outlet abnormalities can be due to lack of support, fibrosis, or neurologic insult.

A positive cough stress test indicates genuine stress incontinence (GSI). In patients with GSI and a positive Q-Tip test, urethral hypermobility is suspected. In patients with GSI and a fixed urethra on Q-Tip test, intrinsic sphincter deficiency is the presumed diagnosis. These patients require complex multichannel urodynamics for further evaluation (see Chapter 116, Urodynamic Testing [Multichannel]).

#### POSTPROCEDURE PATIENT EDUCATION

The results of the testing and various management options should be discussed in detail with the patient. Patients should be instructed to call the clinician's office for pain or hematuria lasting longer than 48 hours and for symptoms of a urinary tract infection. Patients with persistent incontinence despite conservative therapy are candidates for complex urodynamics.

# URODYNAMIC TESTING (MULTICHANNEL)

Jeffrey R. Dell • Grant C. Fowler

Incontinence, dysuria, urinary retention and frequency, and other urinary symptoms are common problems among a growing population, the elderly. Given the broad range of etiologic factors that can cause incontinence (Box 116-1) and other urinary symptoms, accurate diagnosis is the cornerstone for formulating an effective treatment plan. In addition to a careful history and physical examination, urodynamic testing—the study of hydrodynamics and muscle activity to define the functional status of the lower urinary tract—can quantify abnormalities in order to make an accurate diagnosis. Urodynamic testing is also useful for objective assessment of patient improvement after a prescribed treatment protocol.

Although simple urodynamics (see Chapter 115, Bedside Urodynamic Studies), which can be performed in the office setting and provide objective qualitative data, are useful for conservative treatment in the uncomplicated patient, some patients require more precise quantitative analysis of lower urinary tract function. Formal, multichannel urodynamics (MCUD) provides specific quantitative information about detrusor and urethral function during filling, storage, and emptying of urine.

MCUD involves the simultaneous measurement of pressure from multiple sites during bladder filling and emptying and allows precise measurement of intravesical, intraurethral, and intra-abdominal pressure (Fig. 116-1). Complex uroflowmetry measures and graphs urine volume voided over time, allowing detection of anatomic (obstructive) and physiologic (functional) voiding abnormalities. Complex cystometry, a filling test of the bladder, measures and graphs the pressure–volume relationship of the bladder as it distends and

contracts, determining abnormalities of detrusor activity, sensation, capacity, and compliance consistent with urge incontinence or detrusor instability. *Urethral pressure profilometry* evaluates the urethral continence mechanism as a possible cause of stress urinary incontinence (SUI). *Pressure–flow studies* allow determination and quantification of a patient's voiding mechanism, helping establish the etiology of voiding dysfunction. *Electromyography* (EMG) evaluates contractile activity and innervation of the perineal muscles involved with voiding. *Bethanechol testing* can be used to diagnose a neurogenic bladder. If a contrast medium is used for the infusion, a *voiding cystourethrogram* can be performed.

When performing MCUD, bladder ( $P_{ves}$ ) and urethral ( $P_{ura}$ ) pressures are measured directly with a single intravesical catheter that contains two microtransducers, one located in the bladder and the other in the urethra. A separate, single microtransducer catheter is placed in either the rectum or the vagina and indirectly measures simultaneous intra-abdominal pressure ( $P_{abd}$ ). Detrusor pressure ( $P_{det}$ ) and urethral closure pressure from a second measured pressure. Detrusor pressure is derived by subtracting intra-abdominal pressure from intravesical pressure ( $P_{det} = P_{ves} - P_{abd}$ ), whereas urethral closure pressure is the difference between urethral pressure and intravesical pressure ( $P_{ucp} = P_{ura} - P_{ves}$ ; Fig. 116-2).

#### **DEFINITIONS**

Valsalva leak point pressure (VLPP): The pressure required to open the urethra.

Urethral pressure profile (UPP): The pressure along the functional length of the urethra. The maximal urethral closure pressure (MUCP) is recorded as maximal pressure minus the baseline urethral pressure ( $P_{ura}$ ). It reflects the highest pressure the sphincter has at rest in order to keep it closed.

Intravesical pressure ( $P_{ves}$ ): The pressure within the bladder.

Intra-abdominal pressure ( $P_{abd}$ ): The pressure surrounding the bladder. It is approximated by the pressure within the rectum or the vacina.

Detrusor pressure ( $P_{der}$ ): The component of the intravesical pressure that is created from the force in the bladder wall alone. It is estimated by subtracting intra-abdominal pressure from intravesical pressure. The simultaneous measurement of both intra-abdominal and intravesical pressure is required to obtain this measurement.

*Urethral pressure*  $(P_{um})$ : The pressure within the urethra, which reflects both the urethral closure pressure and the vesical pressure. *Functional bladder capacity*: The amount of urine the bladder can hold under natural conditions.

Cystometric capacity: A subjective measure of the total volume of fluid the patient can tolerate comfortably during bladder filling.

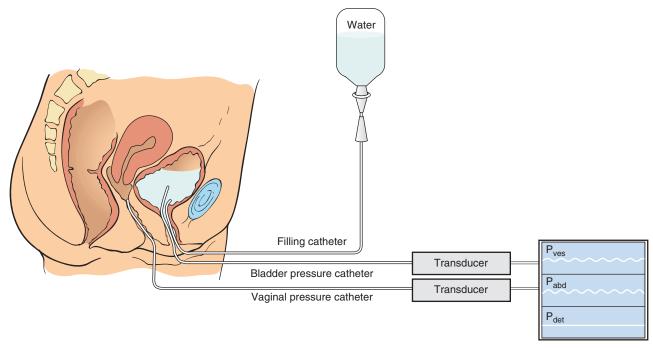

Figure 116-1 Multichannel urodynamics (MCUD) with measurement of vesical and abdominal pressure using separate catheters.  $P_{abd}$ , intra-abdominal pressure;  $P_{det}$ , detrusor pressure;  $P_{ves}$ , bladder pressure.

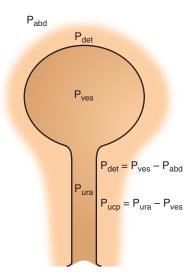

#### **INDICATIONS**

#### **History**

- Mixed incontinence
- Unclear etiology of incontinence
- Continuous leakage
- Coexisting neurologic disorder or diabetes
- Male patients (frequently require MCUD)

#### After Bedside Urodynamic Studies

- Simple cystometry or flowmetry that is ambiguous or inconclusive
- Mixed incontinence results
- Failure of treatment based on bedside urodynamics results

**Figure 116-2** Mathematical formulas deriving detrusor pressure and urethral closure pressure from multichannel urodynamics measurements.  $P_{abd}$ , intra-abdominal pressure;  $P_{det}$ , detrusor pressure;  $P_{ucp}$ , urethral closure pressure;  $P_{ura}$ , urethral pressure;  $P_{ves}$ , bladder pressure.

#### **Stress Incontinence**

- Before surgical correction (especially if patient is high surgical risk)
- Potential SUI with significant pelvic prolapse
- Recurrent incontinence after previous surgery for SUI

#### **Therapeutic Failures**

- Urge incontinence
- Frequency, urgency, and pain syndrome
- Nocturnal enuresis

#### Miscellaneous

- Lower urinary tract dysfunction after pelvic radiation
- Lower urinary tract dysfunction after radical pelvic surgery
- To monitor treatment precisely

#### **CONTRAINDICATIONS**

- Untreated cystitis
- Unevaluated and untreated gross hematuria
- Uncooperative patient
- Inability to tolerate urinary catheterization

There are few contraindications to MCUD. Patients with active cystitis or gross hematuria should be evaluated and treated before urodynamic testing. Patients who are unable to tolerate urethral catheterization or are uncooperative in the office setting should not be considered candidates for MCUD testing.

#### **EQUIPMENT**

- Nonsterile gloves
- Commode with attached uroflowmetry instrument
- Adjustable urodynamics chair (recommended)
- Urodynamics unit (includes cystometer and uroflowmeter) with printer
- Microtip or dual-lumen measuring catheters

- Intravenous pole with 1-L bag of room-temperature infusion solution (sterile water, saline, lactated Ringer's solution, or radiographic contrast media)
- Iodine swabs
- Water-based lubricating gel (nonanesthetic)
- Red rubber urinary catheter or 14-Fr straight catheter
- Sterile urine specimen container
- Urinalysis Chemstrips
- Roll of tape (to secure the measuring catheters in place)
- Large cotton-tipped applicators or vaginal speculum (to reduce uterine prolapse)

#### PREPROCEDURE PATIENT PREPARATION

All patients should be counseled regarding the indications, techniques, and complications associated with urethral catheterization (see the sample patient education form available online at www. expertconsult.com). Clear communication and instructions improve patient comfort during testing, thereby improving the results obtained. Patients should be instructed to come to the office with a full bladder to maximize information obtained from initial uroflowmetry. Each step of the procedure should be carefully explained to the patient before proceeding. Drug allergies should be noted before prescribing prophylactic antibiotics or phenazopyridine. Patients will be asked about symptoms and their usual voiding pattern during the testing.

#### **TECHNIQUE**

Clinicians should follow universal blood and body fluid precautions when performing this procedure. Because the primary goal of MCUD is to reproduce and quantify the patient's symptoms, patients should be asked if their usual voiding pattern and their symptoms are reproduced during testing.

#### **Complex Uroflowmetry**

- The patient is asked to come to the office with a full bladder because urine flow parameters depend on the volume voided (the patient should void at least 150 mL, and preferably 200 mL, for the test to provide reliable data).
- 2. In a relaxed, private setting, the patient is instructed to void into a commode with a uroflow instrument attached (Fig. 116-3). Uroflowmetry measurements, including time and flow rate, are recorded with the urodynamic unit set to "uroflowmetry."

#### **Complex Cystometry**

- 3. After the patient has voided, place him or her in the sitting position and cleanse the external urethral meatus with iodine swabs. Insert the lubricated tip of the red rubber catheter into the bladder lumen. The residual urine is drained into the sterile specimen container and the postvoid residual volume is recorded. The red rubber catheter is then removed and dipstick urinalysis is routinely performed. In patients with a positive test for leukocytes, MCUD should be postponed until after treatment of the urinary tract infection. The catheterized specimen may be sent for urine culture.
- 4. Turn on the urodynamic unit and printer and attach the pressure catheters to the appropriate channels. Connect the bladder catheter infusion port to the intravenous tubing of the infusion solution, which is attached to a water pump to regulate flow (Fig. 116-4).
- 5. Calibrate the urodynamic unit by flushing all bubbles from the catheters with infusion solution and setting all channels to zero. Introduce the bladder catheter into the bladder through the external urethral meatus with the microtransducer at the 3

**Figure 116-3** Typical complex uroflowmetry setup with commode and uroflow instrument.

Figure 116-4 Complex cystometry setup with fluid, water pump, multichannel transducers, computer, and recording device.

TABLE 116-1 Correlation of Interval Bladder Sensations to Normal Experiences					
	Sensation	Normal Volume (mL)	Life Circumstance		
First Second Third Fourth Fifth	Awareness of bladder filling Normal desire to void Strong desire to void Urgent desire to void Maximum capacity	100–200 200–300 300–400 400–600	While watching TV, aware that urine is in the bladder Sensation that the patient would usually and normally empty his or her bladder Patient would attempt to hold urine during good TV program Patient would go straight to the bathroom at a department store during a sale Patient would consider pulling the car off the road to urinate in the woods		

o'clock position. Take care to place the proximal transducer near the midurethra. Then place the abdominal catheter into the rectum or the vagina. If a woman has pelvic prolapse beyond the hymenal ring, the probe should be placed into the rectum. The catheters are secured to the patient's inner thigh with tape. In women with significant prolapse, to reduce artifact, even if the probe is placed in the rectum, we recommend performing the cystometry with the prolapse reduced using a large cotton-tipped applicator.

- 6. Activate the cystometrogram recording device and ask the patient to cough to confirm correct placement. A cough should produce a pressure spike on both the intra-abdominal and the intravesical tracings. The bladder is then filled with infusion solution at a medium fill rate, which is usually 50 mL/min (but can be 10 to 100 mL/min).
- 7. Record bladder volumes corresponding to first sensation, normal desire to urinate, strong desire, urgency, and maximum bladder capacity. This is most easily accomplished by correlating bladder sensations with normal experiences (Table 116-1). Instruct the patient to periodically cough (cough stress test), and inspect the external urethral meatus for sudden urine loss. Determine the minimum volume at which leakage occurs (when leakage is first noted). If leakage is continuous, it can usually be minimized with gentle traction on the catheter or by manual occlusion of the male penile urethra to obtain maximum bladder capacity.
- 8. The infusion should be stopped when a contraction occurs or any leakage is noted, after which the infusion should be restarted. Continue bladder filling until bladder pressure shows a progressive rise above baseline (reduced compliance) or maximum bladder capacity. At maximum bladder capacity, the patient usually has a contraction and he or she should be asked to try to inhibit the contraction, a test for detrusor instability of hyperreflexia. If no images or pressure flow studies are needed, the catheter is then opened and the infusion solution drained.

# **Urethral Pressure Profile and Functional Urethral Length**

9. After completion of the cystometry, a urethral pressure profile and functional urethral length (UPP/FUL) is recorded by graphing the pressure while pulling the transducer from the internal to the external urethral meatus at a constant speed (usually 0.5 cm/sec). It can be pulled by hand or with a mechanical pulling device. This test commonly uses a transducer-containing, side-hole catheter that is perfused at 2 mL/min. Multiple measurements can be performed by reinserting and withdrawing the pressure catheter. The MUCP is calculated by subtracting the baseline urethral pressure from the maximum (Fig. 116-5).

#### **Pressure-Flow Studies**

10. If a pressure–flow study is required to evaluate voiding dysfunction, the catheters are left in place and the patient is instructed to void into the commode. Intravesical, intra-abdominal, and intraurethral pressures are measured and, using subtraction analysis, the mechanism of voiding is evaluated.

#### Electromyography

11. Contractile activity and innervation can be checked using EMG. Surface electrodes (including anal-vaginal plugs) are usually adequate for checking contractile activity, especially in children. Needle electrodes are usually necessary for checking innervation.

#### **Bethanechol Testing**

12. For an acontractile bladder, subcutaneous bethanechol (5 mg in patients weighing >75 kg, or 0.3 mg/kg) can be used to determine if a neurogenic bladder is the cause. Cannon's law of denervation supersensitivity suggests that a denervated organ produces an exaggerated response to its natural neurotransmitter. To perform the test, baseline cystometric pressures should be measured with the bladder filled to 100 mL, and then the bladder drained. About 15 minutes after administering subcutaneous bethanechol (in those for whom it is not contraindicated), there will be evidence of its systemic effect with increased salivation and flushing. At that time, an increase in pressure of 20 cm H<sub>2</sub>O over baseline when the bladder is again filled to 100 mL suggests supersensitivity due to denervation. Atropine 0.4 mg (given intramuscularly) should be available to reverse bethanechol if necessary.

#### **COMPLICATIONS**

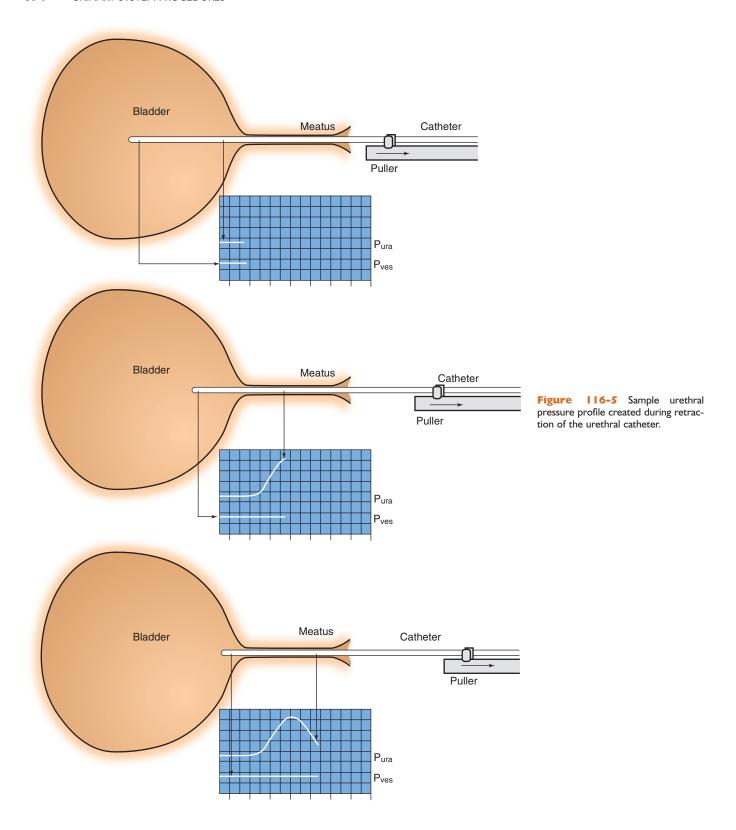

- Bladder infection
- Gross hematuria

Like bedside urodynamics, MCUD is associated with few complications. In rare cases, patients may develop a urinary tract infection after the procedure. Routine prophylactic antibiotics as well as phenazopyridine, a bladder analgesic, are recommended after the procedure. Transient gross hematuria may also be noted after the procedure, especially after difficult catheterization in a postmenopausal woman with urethral atrophy. This usually resolves spontaneously within 48 hours. Cystoscopy-urethroscopy should be considered in patients with persistent hematuria or lower urinary tract pain beyond 48 to 72 hours.

#### **INTERPRETATION OF RESULTS**

Given the complexity of the lower urinary tract, results of MCUD should always be correlated with the physical examination and clinical history.

Uroflowmetry, with measurement of a postvoid residual, assesses bladder emptying and evaluates for overflow incontinence. Urine flow rate depends on initial bladder volume. Specific normal flow rates for greater than 150 mL voided have been determined by age and sex (Abrams and Torrens, 1979), and for men younger than 40 years, between 40 and 60 years, and older than 60 years of age, normal rates are 22 mL/sec, 18 mL/sec, and 13 mL/sec, respectively. In women younger than 50 years of age, the flow rate should be greater than 25 mL/sec; in women older than 50 years of age, it should be greater than 18 mL/sec. The normal flow pattern (volume

over time) is bell-shaped (Fig. 116-6) and continuous. An interrupted pattern suggests straining to void or lack of coordination between detrusor muscle contraction and sphincter relaxation. Prolonged voiding times may indicate an obstructed voiding pattern resulting from increased outlet resistance (e.g., urethral obstruction,

Normal values for a postvoid residual are not universally established, but previous investigators have advocated a normal postvoid residual measurement to be less than 200 mL and less than 20% of

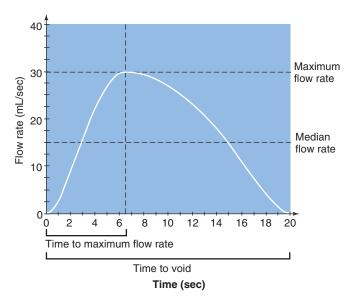

Figure 116-6 Normal uroflow tracing in woman without obstruction.

the total void. Patients with urinary frequency or incontinence and a normal postvoid residual have a bladder storage problem, and this can result from disorders of bladder compliance, involuntary bladder contractions, bladder hypersensitivity, or bladder outlet abnormalities. Bladder outlet abnormalities can be due to lack of support, fibrosis, or neurologic insult.

#### Box 116-2. Bladder Capacity Abnormalities: Diagnoses and Predisposing Conditions Reduced Bladder Capacity Diagnoses Detrusor instability (idiopathic) Detrusor hyperreflexia (neurogenic) Genuine stress incontinence Hypersensitive bladder (sensory urgency) **Predisposing Conditions** Urinary tract infection Interstitial cystitis Bladder tumor Radiation cystitis or fibrosis **Emotional factors** Elevated Bladder Capacity Diagnoses Neuropathy Tabes dorsalis Lumbar spinal disk disease Multiple sclerosis Diabetes mellitus Hypothyroidism Pernicious anemia **Predisposing Conditions** Chronic outlet obstruction Urethral stricture

Previous radical pelvic surgery

Habitual infrequent voiding

Urethral tumor

Cystometry will document abnormalities of bladder sensation and compliance (Box 116-2). With a normal bladder capacity and compliance, the detrusor pressure should remain stable (<15 cm H<sub>2</sub>O change) throughout filling. A rise and decline of the detrusor pressure indicates detrusor instability, which may or may not be associated with observable urge incontinence episodes. A largecapacity bladder due to chronic urinary retention may demonstrate increased compliance with little or no increase in pressure despite a large volume of infusion. A gradual persistent rise in detrusor pressure indicates decreased compliance, with possible causes being chronic inflammation, radiation cystitis, interstitial cystitis, and bladder carcinoma. A gradual persistent rise could also be due to a low-grade contraction. Discontinuing the filling can help differentiate between decreased compliance and a low-grade contraction; the pressure stops rising or falls slightly with decreased compliance. Sudden urine loss associated with periodic coughing or Valsalva maneuver during filling cystometry is diagnostic of SUI (Fig. 116-7).

Most patients can suppress a detrusor contraction completely, if asked to do so, even when the bladder is very full. Detrusor overactivity usually declares itself with a contraction when less than 200 mL has been infused. If there is a known neurologic lesion preventing this inhibition, it is known as detrusor hyperreflexia. The term detrusor instability is usually reserved for non-neurogenic or idiopathic causes. Acontractile detrusor is defined by an inability to contract the detrusor when it is full. However, in 10% of men and 50% of women, acontractile detrusor is due to psychological inhibition, one of the most common causes for overinterpretation of MCUD. Bethanechol testing should be used if a neurogenic bladder is suspected as the cause of acontractile detrusor.

**Figure 116-7** Typical complex cystogram tracing in woman with mixed incontinence, detrusor instability (at 320 mL), and genuine stress urinary incontinence (GSUI) (at 480 mL).

TABLE 116-2 Normal Values for MUCP and FUL					
	Age (yr)	MUCP (cm H <sub>2</sub> O)	FUL (cm)		
Male	≤50	65–105	3.5–4.5		
	>50	65–105	4.0–4.5		
Female	≤50	60–90	2.0–3.5		
	>50	50–80	2.0–3.5		

FUL, functional urethral length; MUCP, maximal urethral closure pressure.

Urethral pressure profiles and urethral length provide static evaluation of the urethral sphincter mechanism. MUCP values less than 20 cm H<sub>2</sub>O are consistent with intrinsic sphincter deficiency, and values between 20 cm H<sub>2</sub>O and normal are considered borderline. Normal values for both MUCP and FUL are listed in Table 116-2, and Figure 116-8 shows a normal urethral pressure profile curve as well as demonstrating FUL. In men, the FUL normally increases with age, whereas the MUCP decreases with age in women.

#### POSTPROCEDURE PATIENT EDUCATION

After MCUD testing, results should be reviewed in detail with the patient. The diagnosis should be confirmed on the basis of careful review of the urodynamic tracing, and management options should be discussed. Patients with voiding dysfunction may benefit from urethral dilation, smooth muscle relaxants, or intermittent selfcatheterization. For patients who demonstrate detrusor instability or reduced bladder capacity with coexisting overactive bladder symptoms, nonsurgical treatment modalities, including anticholinergic medications, bladder retraining, dietary modification, and neuromodulation, should be considered. Patients with SUI should be offered both surgical and nonsurgical treatment modalities (see Chapter 153, Pessaries), depending on the severity of their incontinence, the anticipated outcomes, and surgical risk factors.

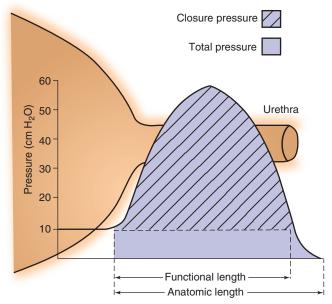

Figure 116-8 Normal urethral pressure profile curve. Functional urethral length is also demonstrated.

# ADULT CIRCUMCISION

John R. Holman

Adult circumcision is a procedure about which little is written, even in urologic literature. It is often performed for reasons that are not purely medical, yet it also has clearly defined medical indications. Some patients have their own nonmedical reasons.

General anesthesia may be necessary, but usually local anesthesia is sufficient in the outpatient setting, including the properly equipped office. Informed consent should be obtained after a thorough discussion with the patient (and partner, if appropriate), during which the indications, procedure, postprocedure care, and potential complications are explained. (See the sample patient education and consent forms online at www.expertconsult.com.) This consent is required for all patients, and it must always be documented to serve as a record of the authenticity of the patient's presenting symptoms. Thorough documentation is important because individual physicians may vary in their judgments of surgical necessity. The physician must make sure that the patient's reasons for requesting circumcision are medically sound and that the patient's expectations of the results are realistic. There is evidence circumcision does not change sexual experience or satisfaction.

#### **ANATOMY**

Identify normal male anatomy before proceeding. Patients with an occult hypospadias or epispadias should be referred to a urologist.

#### **INDICATIONS**

- Phimosis (tightness of the foreskin so that it cannot be drawn back from over the glans); possibly related to complaints of pain with erections and intercourse
- Paraphimosis (retraction of a narrow, inflamed foreskin that cannot be replaced)
- Penile hygiene; recurrent balanitis (inflammation of the glans penis)
- Posthitis (inflammation of the prepuce) not relieved by medical treatment
- Preputial neoplasms (e.g., erythroplasia of Queyrat, which is severe squamous dysplasia)
- Excessive foreskin redundancy
- Frenular tears
- Patient or partner preference after informed discussion

Patients may also have social, religious, or personal reasons for requesting a circumcision. Exploration of these reasons ensures a thorough understanding of the risks and benefits as well as alternatives to the procedure. Circumcision can reduce the rate of human immunodeficiency virus infection by 50% to 60% and decreases penile human papillomavirus infection. However, it does not appear to prevent other sexually transmitted infections.

#### **CONTRAINDICATIONS**

#### **Relative**

- Psychiatric disorder or history (relative contraindication; these patients must be screened carefully)
- Bleeding dyscrasias (evaluate appropriately)
- History of penile surgery, significant trauma, or unusual-appearing or ambiguous genitalia (consider a referral to a specialist)

#### Absolute

- · Active inflammation in the genital area
- Infection in the genital area

#### **EQUIPMENT AND SUPPLIES**

- 10-mL syringe with a 1- to 1½-inch, 27-gauge needle and a ½-inch, 30-gauge needle
- Prep bowl with a dozen 4 × 4 gauze sponges
- Iodine solution or other antiseptic for scrub
- Ring forceps
- Pack of sterile 4 × 4 gauze bandages
- One fenestrated drape
- 6-inch segment of half-inch Penrose drain
- Six straight mosquito forceps
- One large straight forceps
- One curved Mayo scissors
- One medium-size straight Metzenbaum scissors
- One suture scissors
- 5-inch needle holder
- One Brown-Adson thumb forceps
- 4-0 or 5-0 absorbable suture (e.g., Vicryl, Dexon)
- Petrolatum gauze
- 1-inch Kling bandage
- One malleable 4- to 6-inch silver probe (optional)
- Needle-tip electrocautery unit
- Sterile marking pen

# PREPROCEDURE PATIENT EDUCATION AND FORMS

The patient should be properly counseled and evaluated before the surgery. A patient education handout is provided, and a consent form is signed. (See the sample patient education and consent forms online at www.expertconsult.com.) If the patient is anxious, a preprocedural dose of an oral, sublingual, intramuscular, or intravenous anxiolytic (e.g., diazepam 10 mg) may be administered. If such a dose is used, someone must drive the patient home after the procedure. (See the sample patient education handout online at www.expertconsult.com.)

#### **PROCEDURE**

The patient should be supine and comfortable. Shaving and clipping of hair should be avoided to minimize the infectious complications. Surgically prepare the entire genitalia, scrotum, and pubic area with an appropriate antiseptic solution. Use a fenestrated drape.

#### **Anesthesia**

#### Ring Block

- 1. Using a 10-mL syringe filled with 1% lidocaine *without* epinephrine and a 1-inch, 27-gauge needle, inject 0.5 to 1 mL subcutaneously over the superficial dorsal vein so that the wheal is raised at the junction of the penis and the pubis (Fig. 117-1).
- 2. Without withdrawing the needle, angle it toward both sides of the dorsal vein and inject additional lidocaine.
- 3. Extend the needle subcutaneously downward to the deep fascia of the penis—an area of firm resistance—and continue injecting

- circumferentially, staying close to the deep fascia of the penis. The penile skin is loose; therefore, complete circumferential deployment of the anesthetic agent can be accomplished, and the ventral surface can be reached from both sides. This is called a *ring block*. Inject approximately 4 mL in this manner on each side. Do not penetrate the fascia.
- 4. Wait a few minutes, and then inject 1 mL of the local anesthetic subcutaneously into the frenulum using a ½-inch, 30-gauge needle (Fig. 117-2).
- 5. Wait several more minutes and then test the depth of local anesthesia by cautiously grasping the edge of the foreskin with a mosquito hemostat. Should more anesthesia be required, use a Penrose drain as a tourniquet around the midportion of the penis. Tie the tourniquet tightly or hold the Penrose drain with a clamp to obstruct venous return. Inject an additional 2 mL of lidocaine into both corpora cavernosa just distal to the tourniquet (Fig. 117-3).
- 6. After approximately 5 minutes, retest for anesthesia; if anesthesia is adequate, remove the tourniquet.

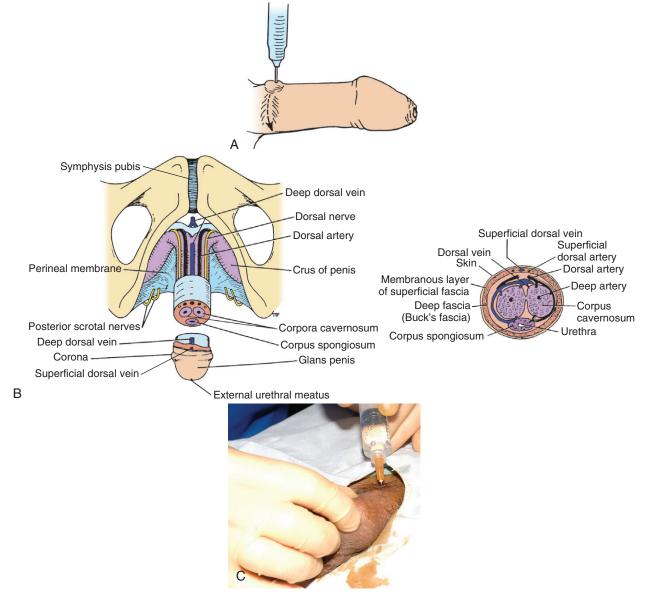

Figure 117-1 Ring block of the penis. **A,** Site of initial injection over dorsal vein. **B,** Cross-sectional view of the penis. **C,** Operative view. (**B,** From Snell RS, Smith MS: Clinical Anatomy for Emergency Medicine. St. Louis, Mosby, 1993.)

Figure 117-2 Additional anesthetic injected into the frenulum.

#### **Dorsal Penile Nerve Block**

As an alternative to or in addition to the ring block, the surgeon may perform a *dorsal penile nerve block*. The dorsal penile nerve is blocked by injecting local anesthetic solution deep to Buck's fascia, where the nerves emerge from under the pubic bone (see Fig. 117-1B).

- 1. The patient is placed in the supine position.
- 2. After preparation of the skin, two injection sites are identified over the inferior edge of the pubic bone at approximately the 10 and 2 o'clock positions relative to the base of the penis.
- 3. A 27-gauge (1½-inch) needle is inserted directed ventrally until the pubic bone is contacted.
- The needle is "walked" caudad off the pubis and through Buck's fascia.
- 5. After aspiration, 5 mL of local anesthetic is injected at each site. A mixture of equal volumes of 0.5% bupivacaine (Marcaine) and 1% or 2% lidocaine without epinephrine provides rapid onset of anesthesia and suitable duration for circumcision.

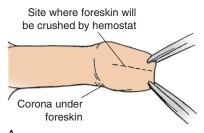

#### **Dorsal Slit Technique**

The dorsal slit technique is preferred if the patient has phimosis or paraphimosis. An assistant is of considerable help in carrying out this procedure.

- 1. Using small straight hemostats, grasp the distal foreskin at the 11, 1, 5, and 7 o'clock positions, and gently pull the foreskin over the glans
- 2. Use a malleable silver probe or the hemostats on the undersurface of the dorsal foreskin to determine a point 1 cm distal to the corona.
- 3. Place a large straight hemostat at the 12 o'clock position, close it firmly, and compress and crush the foreskin to the point that you previously determined with the silver probe (Fig. 117-4). Repeat this procedure of clamping at the 6-o'clock position, going up to the base of the frenulum.
- 4. After the dorsal and ventral areas are clamped, mark a line where the circumferential excision of the foreskin is to occur. Use a marking pen to connect the dorsal point with the inferior point on each side.

**Figure 117-3** Injection of anesthetic into corpora cavernosa with tourniquet applied.

**Figure 117-4** Straight hemostats (four) applied at the dorsal and ventral aspects of the tip of foreskin at the 11, 1, 5, and 7 o'clock positions. **A,** Schematic. **B,** Operative view.

- 5. After 5 or more minutes (time it by the clock), remove the forceps and use a straight Metzenbaum scissors to incise through the *center* of the crushed areas (Fig. 117-5). Crushing the tissue reduces the bleeding from this incision.
- 6. Using a curved Mayo scissors, carefully excise these two lateral tissue flaps, *maintaining a 1-cm margin from the corona*, except at the frenulum, where the foreskin is tapered only 2 to 3 mm (Fig. 117-6). Fulgurate all bleeders or tie with a 5-0 plain catgut.
- 7. If the large dorsal vein is cut, ligate with absorbable sutures.
- 8. After complete hemostasis, sew the outer layer of skin just proximal to the glans to the underlying mucosal layer (1-cm skin remnant of prepuce) with multiple 4-0 or 5-0 absorbable sutures (Fig. 117-7). If performing the procedure alone, leave some sutures long dorsally. These can be used (and cut off later) for retraction to stabilize the penis when suturing ventrally. Use hemostats to fix the long suture to the drape.
- 9. Place two layers of petrolatum gauze dressing, which is nonadherent, over the suture line around the entire circumference and overlay with a light layer of Kerlix or Kling (Fig. 117-8).

#### Sleeve Technique

The sleeve technique uses two circumferential incisions. One is made on the internal aspect of the foreskin distally, near the coronal sulcus. The other is made on the external part of the foreskin proximally and defines an amount of prepuce removed. A "sleeve" of tissue between the two incisions will be excised.

- 1. The external preputial incision is outlined with a marking pen at the level of the corona (Fig. 117-9A and B).
- 2. After retracting the foreskin, the internal preputial incision is marked with the pen approximately 1 cm proximal to the coronal sulcus. It is important to apply gentle downward pressure on

Figure 117-5 Cutting through crushed tissue.

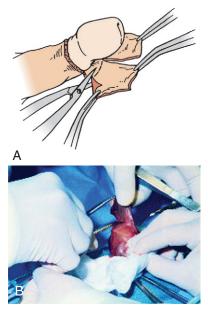

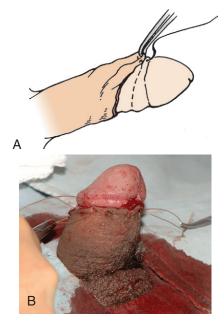

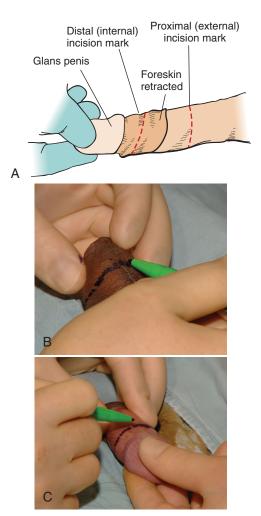

Figure 117-6 Excision of foreskin. A, Schematic. B, Operative view.

**Figure 117-7** Suturing of the skin to the shaft mucosa just proximal to the corona. **A,** Schematic. **B,** Operative view.

Figure 117-8 Suture covered with gauze dressing.

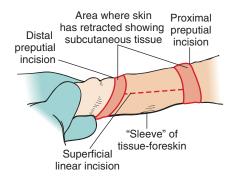

**Figure 117-9** External and internal preputial skin incision sites are marked. **A,** Schematic. **B,** Operative view, internal incision mark. **C,** Operative view, external incision mark. (**A,** Redrawn from images in Holman JR, Stuessi KA: Adult circumcision. Am Fam Physician 59:1514–1518, 1999.)

the *prepubic* fat pad at the base of the penis while making the initial outlines to remove the correct amount of skin (Fig. 117-9A and C).

- 3. The external proximal *circumferential* preputial incision is made with the scalpel and carried to Buck's fascia.
- After retracting the foreskin, a second circumferential incision is made in the inner prepuce at the previous mark. The internal incision is carried straight across the frenulum ventrally.
- A sleeve of tissue now exists between the two incisions. This sleeve is the foreskin. Hemostats are placed dorsally for traction (Fig. 117-10).
- 6. After making a superficial linear incision on the sleeve with the electrocautery tool, subcutaneous attachments are separated between Buck's fascia and the prepuce. The sleeve is excised with electrocautery (Fig. 117-11).
- 7. The frenulum is reapproximated initially with the "U" stitch.
- 8. Four quadrant sutures are placed on the dorsum and both sides, and the remaining interrupted sutures are placed at 4- to 7-mm intervals (see Fig. 117-7).
- 9. A sterile dressing of petroleum gauze can be applied (see Fig. 117-8).

#### SAMPLE OPERATIVE REPORT

See the sample operative report online at www.expertconsult.com.

**Figure 117-10** After incisions are made, a "sleeve" of preputial skin remains. The shaded *(pink)* areas show where the skin has retracted, showing subcutaneous tissue. (Redrawn from images in Holman JR, Stuessi KA: Adult circumcision. Am Fam Physician 59:1514–1518, 1999.)

#### **COMMON ERROR**

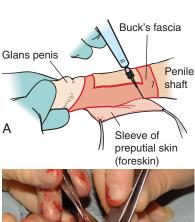

Removal of too much or too little foreskin is a common error. Correct planning of the incision is crucial to avoid this mistake.

#### **COMPLICATIONS**

- Bleeding—direct pressure, cautery, or suture ligature can be used.
- Hematoma—avoid with management of bleeding before skin closure. Apply pressure.
- Infection—sterile technique during surgery is important.
- Pain with erection—prevented by leaving an adequate "cup" (1-cm margin) of coronal skin (see step 6 under the "Dorsal Slit Technique" section).
- Stricture and scarring (rare).
- Dehiscence resulting from nocturnal erections (see next section).

#### POSTPROCEDURE MANAGEMENT

 Prescribe 5 days' worth of adequate analgesics appropriate for the patient's pain tolerance. A combination product containing codeine (such as Tylenol no. 3), a nonsteroidal anti-inflammatory

**Figure 117-11** Sleeve excised with electrocautery, tissue scissors, or scalpel. **A,** Schematic. **B,** Operative view. (**A,** Redrawn from images in Holman JR, Stuessi KA: Adult circumcision. Am Fam Physician 59:1514–1518, 1999.)

- drug, or a similar product is sufficient. Topical 5% lidocaine ointment can also be helpful.
- Instruct the patient to soak in a tub of warm water 24 to 36 hours later and to remove all of the dressing at that time. Replace the dressing daily after soaking off.
- One ampule of amyl nitrate (crush and inhale one to six times as needed; may be repeated once after 5 minutes) can be used as abortive therapy for erections during the 1-week recovery period.

#### POSTPROCEDURE PATIENT EDUCATION

- Instruct the patient on how to replace the petroleum gauze and Kling gauze, which should be done every day until the patient returns to the office for the follow-up visit in 1 week.
- Tell the patient to call if there is any undue pain, active bleeding, or signs of infection (e.g., streaks of redness, fever, purulent drainage).
- Instruct the patient to avoid sexual arousal and sexual intercourse for about 4 weeks.

# **ANDROSCOPY**

John L. Pfenninger

Androscopy is an office procedure mainly used to identify condylomata. It examines the male genitalia under magnification after acetic acid has been applied. It can be used to evaluate any dermatologic disorder/lesion in the genital areas and also to ensure complete removal of lesions. Another term for this procedure is *penoscopy*.

Recent literature documents that the human papillomavirus (HPV) is the cause of cervical dysplasia and cervical cancer. Whether the virus *alone* leads to cancer is unknown. Yet, HPV is the necessary, if not the single sufficient cause for cervical cancer. HPV is very contagious and it is most readily spread through sexual contact. Intromission is not necessary because skin-to-skin contact is enough. It may also be transmitted in yet-unknown ways in a minority of cases. Fomites do not transmit the disease. Condoms provide only partial protection from HPV but do help prevent spread.

The clinical significance of condylomata and HPV in men is less serious than it is in women, but men act as carriers and may transmit the disease to sexual partners. Although rare, HPV can cause penile carcinoma. Anal-receptive homosexual men have 50 times the rate of anal carcinoma compared to the incidence in the average population. An increased rate of anal carcinoma in anal-receptive women can also be anticipated, but there is no literature to document this.

There are over 100 types of HPV. Eight to 10 of these characteristically infect the genital areas. Condylomata acuminata, the visible lesions that we commonly see, are caused by noncarcinogenic strains, such as types 6 and 11. The subclinical types, identified only by examination under magnification after acetic acid staining, are more likely to cause neoplastic changes; frequently these are types 16 and 18. (See Chapter 137, Colposcopic Examination, Chapter 142, Human Papillomavirus DNA Typing, and Chapter 155, Treatment of Noncervical Condylomata Acuminata.)

There is no evidence that treatment of male partners of women who have dysplasia lessens the likelihood of persistence or recurrence in the woman. It is uncertain why condom use is beneficial because the infection is a regional disease. In men, it is present on the penis, scrotum, perineum, and perianal areas. What is visible is only a focal manifestation of a diffuse involvement. In women, it is present on the cervix, vagina, vulva, and the perineal and perianal areas. Winer and colleagues (2006), however, in a well-designed study showed significant protection in women with consistent condom use by their male partners.

Some clinicians question the value of carrying out an androscopic examination. Identification and treatment of condylomata is not the only reason to perform androscopy. Patient education is perhaps the most valuable aspect of this procedure. The man must be informed of the significance of his disease and the necessity of maintaining a single-partner committed relationship. It is no longer a matter of moral or religious persuasion, but rather a good health practice to be monogamous (as are exercising, not smoking, eating low-fat foods, and so forth). Men spread the disease even when visible lesions are not apparent. Only through education can they change their habits.

Men who have HPV can affect their partners in several ways. Not only do they spread the virus by skin-to-skin contact, but HPV has been shown to be present in the semen and in the sperm cell itself. Men who smoke have nicotine and its byproducts in their ejaculate as well as on their hands (important during manual stimulation), which may be a cofactor in HPV persistence. Those who are subject to passive smoking have lower folate levels—a known risk factor for cervical cancer.

The common factors for penile carcinoma include lack of hygiene, sex outside of marriage, smoking, and HPV infection. Clinically differentiating mild, moderate, and severe dysplasia of the penis (penile intraepithelial neoplasia [PIN]) is nearly impossible without obtaining biopsy samples. Anorectal cancer frequently contains the HPV, and some now recommend obtaining a Papanicolaou (Pap) smear of the pectinate (dentate) line on a regular basis to detect anal dysplasias in high-risk individuals. High-resolution anoscopy (HRA), which uses magnification (usually a colposcope) and acetic acid staining, can identify precursor lesions for treatment (see Chapter 99, High-Resolution Anoscopy).

#### **INDICATIONS**

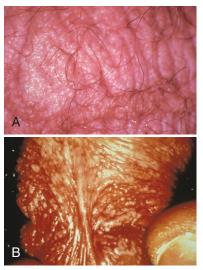

- Visible condylomata on the penis, scrotum, or anus. Staining and examination with magnification will identify smaller lesions that are easier to treat and often not visible to the naked eye. This is likely to decrease recurrences. Androscopy also confirms that the entire lesion has been removed when surgical or ablative therapies are used. Early and complete treatment may reduce the recurrence of the disease. Figure 118-1 shows an example of large condylomata. Examination under magnification will aid in completing removal once the bulk of the lesion has been removed and also identify any smaller lesions that are not immediately obvious. Completing the removal under magnification helps in limiting the depth of excision because penile skin is so thin.
- Partner with recurrent or persistent condylomata acuminata or cervical dysplasia. There is some evidence that if the male partner presents with a high viral load, the immune system response of his partner may be overwhelmed by the virus. High viral load may exist if the man has extensive visible acuminate lesions or a diffuse acetowhite staining of the penis (Fig. 118-2).
- Psychological reassurance.
- Chronic perineal or perianal irritation.
- Recurrent condylomata. This could be from incomplete previous removal or failure to identify smaller lesions.
- Medical-legal examinations in child abuse cases.
- History of other sexually transmitted infections. Although rarely performed for this reason, androscopy with a negative result helps reassure patients that currently there are no HPV lesions.
- Necessity for patient education. Performing a procedure is better received by the patient than just "coming in to talk." A biopsyproven diagnosis speaks a thousand words of reinforcement.
- Penile lesions of uncertain significance.

Figure 118-1 Large condylomata. (Courtesy of John L. Pfenninger, MD, The Medical Procedures Center, PC, Midland, Mich.)

#### **EOUIPMENT**

- Spray bottle with 5% acetic acid (white vinegar).
- Colposcope (or a high-quality hand-held magnifying lens).
- High-quality fine tissue scissors (e.g., 5-inch curved Metzenbaum scissors) or sharp dermal curettes to obtain a biopsy/remove lesions.
- Pickups.
- Formalin jars.
- Aluminum chloride (Drysol) for hemostasis. Monsel's solution may cause an extended period of hyperpigmentation but is also acceptable.
- 1 to 5 mL lidocaine 1% or 2% without epinephrine.
- 30-gauge needle.
- 1- to 5-mL syringe (depending on size and number of lesions).
- Radiofrequency unit with smoke evacuator, 85% trichloroacetic acid (TCA), or an infrared coagulator if condylomata are to be treated. (See Chapter 155, Treatment of Noncervical Condylomata Acuminata.)

**Figure 118-2 A,** White epithelium seen on the scrotum after application of 5% acetic acid. **B,** Condylomata seen on the penis after application of 5% acetic acid. Lesions were not visible before staining. (Courtesy of John L. Pfenninger, MD, The Medical Procedures Center, PC, Midland, Mich.)

#### PREPROCEDURE PATIENT PREPARATION

It is always best if the patient is well informed about the nature of the disease before the procedure. Provide the patient with educational material. Prior to the visit, encourage the patient to watch a 21-minute videotape (available from Creative Health Communications/The National Procedures Institute, Midland, Mich) that discusses the implications of HPV infection in men and women. Viewing the videotape will help the patient focus on questions that he or his partner may have, and it will allow the practitioner to avoid repetitious explanations of the same counseling information. Written handouts are also available from many organizations. No preoperative medication is needed for the procedure, and the patient can be reassured that there will usually be minimal discomfort, even if biopsies are obtained. More discomfort may be experienced should treatment be undertaken, however.

#### **TECHNIQUE**

Although the examination may take only 10 minutes, patients frequently have numerous questions and concerns. Unless the patient is well known to the practitioner, at least 20 minutes should be allotted for this examination—longer if treatment is undertaken.

- 1. After the patient is placed in the examination room, the nurse instructs him to spray the entire genital and anal area with 5% acetic acid (white vinegar) and allow it to soak for 5 minutes.
- 2. Obtain a detailed sexual history (Fig. 118-3, Androscopy Encounter Form).
- Place the patient on an examination table with stirrups, and position as a woman is positioned for a Pap smear. Conduct a visual inspection first and note any lesions.
- 4. Spray the entire genital and perineal area again. Allow the solution to run freely over the perineum and anus.
- 5. Inspect the entire anogenital area under magnification, including the meatus of the penis. Generally a colposcope is used on low power (3× to 5×). Move the penis and scrotum forward and back to bring them into focus (unlike colposcopy, where the cervix is stationary and the scope is adjusted into focus). There is no study comparing good hand-held magnification to colposcopy.
- 6. Grossly apparent warts that were previously seen will generally turn white with the acetic acid. Previously unseen, small, "flat," or subclinical lesions will also now be identifiable on the penis, scrotum, perineum, or rectum. They will show up as white areas, referred to as *acetowhite changes* (see Fig. 118-2).
- 7. Sample any atypical lesions with an unusual vascular pattern (mosaicism or punctation; see Chapter 137, Colposcopic Examination) or pigmentation. The pigmentation in lesions that predicts dysplasia will look different from that of a freckle or nevus; it will be a nondiscrete, brownish discoloration (Fig. 118-4). If no atypical lesions are seen, sample one or two of the acuminate lesions or the acetowhite areas to document the presence of HPV and that there is no dysplasia (Fig. 118-5). It is very convincing to have the pathology report confirm your clinical diagnosis, which reinforces the findings to the patient. It also is not always possible to tell clinically what the lesions are.
- 8. A penile biopsy specimen is easily obtained by using sharp tissue scissors. (A punch biopsy is not needed—you are not sampling the cavernosa!) If only one or two small lesions are to be sampled, simply tent up the skin by pinching it at its base (Fig. 118-6). Looking through the colposcope, obtain a 3- to 4-mm sample with the sharp tissue scissors or remove the entire lesion. No anesthetic is required if only one to two small lesions will be sampled, and this method is often less painful than the injection with anesthesia. Only a very superficial sampling is needed. If the lesions are larger, or more than two samples are to be obtained, it is best to anesthetize with 1% to 2% lidocaine

without epinephrine. Using a 30-gauge needle minimizes any discomfort.

Alternatively, a 3- to 4-mm, disposable, sharp dermal curette can be used for the biopsy or removal. This is a particularly effective method for small lesions, but the curette *must be sharp*. Use disposable units because the reusables are never sharp enough.

- 9. If the condylomata are numerous (see Fig. 118-5), diffuse, or large, they may need to be treated with radiofrequency fine loop surgical removal, ball electrocautery, 85% TCA (Fig. 118-7),
- cryosurgery, 5-fluorouracil (Efudex; Valeant Pharmaceuticals, Aliso Viejo, Calif), imiquimod (Aldara; Graceway Pharmaceuticals, Bristol, Tenn), podofilox (Condylox; Oclassen Pharmaceuticals, San Rafael, Calif), the infrared coagulator, laser, or excisional (shave) therapy. Excision with suture closure is virtually contraindicated. A dorsal penile nerve block may facilitate this removal. (See Chapter 155, Treatment of Noncervical Condylomata Acuminata.)
- Aluminum chloride (Drysol; Person & Covey, Inc., Glendale, Calif), ferric subsulfate (Monsel's solution), or light

**Figure 118-4** Pigmented condylomata. These lesions are more likely to be dysplastic. (Courtesy of John L. Pfenninger, MD, The Medical Procedures Center, PC, Midland, Mich.)

- electrocautery/desiccation may be needed as an astringent to limit postoperative bleeding.
- 11. If only flat, asymptomatic acetowhite changes appear on the penis, anus, or scrotum, treatment is unnecessary, although the biopsies will confirm HPV.
- 12. Unless the patient has had an extensive area of warts treated, he can return to full activity with no modification of his daily routine.
- 13. Sample any lesion of uncertain significance. The differential of penile and anal lesions and the approach to evaluation are noted in Box 118-1 and Figure 118-8.
- 14. Cystoscopy and anoscopy are not routinely recommended for men with condylomata. If lesions are present around the anus and if the man is not anal receptive (which occurs very frequently), treat all perianal lesions first. Anoscopy is indicated but only after resolving the external lesions. Frequently more lesions will be found proximally around the dentate line; these can be removed as biopsies, treated with 85% TCA, frozen, or ablated with ball electrocautery (see Chapter 99, High-Resolution Anoscopy).

#### **PRECAUTION**

Not everything that turns acetowhite (white epithelium) is HPV. Chronic irritation, tinea, and other similar conditions can also appear white after the application of acetic acid.

# Box 118-1. Differential Diagnosis of Anogenital Lesions in Men

#### Infectious Lesions

Chancre

Condylomata acuminata

Condylomata lata

Herpes simplex virus

Molluscum contagiosum

Syphilis

Tinea pubis

### Noninfectious Benign Lesions and Conditions (Including Normal Variants)

Anal polyp

Contact dermatitis

Cyst

Nevus

Normal-variant, papular lesions of the corona (pearly penile papules)

Normal-variant, papular lesions of the frenulum

Seborrheic keratosis

Sentinel "polyp" on a chronic fissure

Skin tags

#### Preneoplastic and Neoplastic Lesions

Bowen's disease (severe dysplasia)

Bowenoid papulosis

Cancer (squamous cell carcinoma of the penis and anus, prolapsing adenocarcinoma of the rectum)

Erythroplasia of Queyrat (squamous cell cancer in situ) Penile intraepithelial neoplasia (PIN I, PIN II, PIN III)

From Pfenninger JL: Androscopy: Examination of the male partner. In Apgar B, Brotzman G, Spitzer M (eds): Colposcopy: Principles and Practice. An Integrated Textbook and Atlas, 2nd ed. Philadelphia, Saunders, 2008, pp 483–496.

#### **COMMON ERRORS**

- Not allowing enough time during the visit to counsel the patient and partner adequately.
- Not performing a complete examination, including retracting the foreskin (Fig. 118-9).
- Sampling or treating a normal variant of the corona, pearly penile papules (Fig. 118-10).
- Failing to perform a biopsy and continuing to treat lesions when they do not respond (Fig. 118-11).
- Using expensive prescription topicals when a simple surgical procedure or application of TCA will quickly and more costeffectively treat the lesion.
- Not using magnification when removing lesions, which increases the likelihood of incomplete removal or missing smaller lesions, thereby increasing the likelihood of recurrence/persistence. Without magnification, it is also more common to perform any removal too deeply, leading to scarring.
- Treating all acetowhite lesions. Even when biopsies confirm the presence of HPV, if the lesions are totally asymptomatic and not visible to the naked eye, treatment is probably unnecessary. Remember that treatment does not eliminate the virus, but only the external manifestations of the disease. It is likely that the virus persists at a subclinical level. There is no evidence that treatment of the male partner in such cases reduces recurrences in female partners.

#### POSTPROCEDURE PATIENT CARE

Topical 5% lidocaine ointment not only soothes the area but prevents treated sites from adhering to the undergarments. A nonsteroidal anti-inflammatory drug (NSAID) is recommended to reduce pain and swelling if more than just a biopsy was done.

No definite recommendations can be made regarding treatment of dysplastic lesions on the penis because studies with long-term follow-up have not been conducted. Between 1% and 5% of the sampled lesions will be reported as mild or moderate bowenoid dysplastic change. Rarely, a severe dysplasia will be found. (Unlike dysplastic cervical lesions in women, it is difficult to predict the degree of dysplastic change observed during the clinical examination, even with magnification, in the man.) In such situations, the patient should return for reexamination in 6 weeks to confirm that the entire dysplastic lesion(s) was removed. The patient should report any unusual growths or ulcerations at once, and he should discuss his HPV history with his physician during future examinations. Sexual partners should be examined and should obtain regular Pap smears. Smoking is strongly discouraged. Supplemental vitamins with folic acid may reduce recurrences. See Chapter 155, Treatment of Noncervical Condylomata Acuminata, for posttreatment patient instructions.

#### **COMPLICATIONS**

Complications are minimal. There may be some depigmentation, scarring, pain, or bleeding, regardless of the technique used. The penile skin is very thin and the biopsy/removal should be kept very superficial. Condylomata acuminata can be confused with other lesions, such as condylomata lata, molluscum contagiosum (commonly seen), keratoses, bowenoid dysplasia, nevi, hemorrhoidal tags, and other nondescript papular lesions. Care must be taken that men do not experience undue psychological difficulty because of HPV infection, but at the same time know that each new sexual partner is at risk of contracting the wart virus and should receive annual Pap smears for several years before going to more lengthy intervals.

#### **CONCLUSION**

Androscopy is a simple procedure to perform that enhances the evaluation and treatment of genital lesions in the male patient. The colposcope is expensive, but if it is available in the office for colposcopic examinations, it can aid male patients also. Studies have not been completed using simple magnification devices, but they may also be an aid. HPV vaccines (Gardasil) for men have just been approved, and appear promising.

#### **PATIENT EDUCATION GUIDES**

See patient education and consent forms available online at www. expertconsult.com.

#### **CPT/BILLING CODES**

There currently is no CPT code for androscopy. Use 55899, unlisted procedure, male genital system (documentation suggested). Insurance companies still rarely pay. Consider charging for a more extended visit with a higher category E&M code (if a new patient or a consult) and for treatment of warts or penile biopsy rather than for "androscopy."

54100 Biopsy, penis, cutaneous

54050 Simple destruction of penile lesions: chemical

54055 Simple destruction of penile lesions: electrosurgical

54056 Simple destruction of penile lesions: cryocautery

54057 Simple destruction of penile lesions: laser

54060 Simple destruction of penile lesions: excision 54065 Destruction of penile lesions, extensive, any method

54105 Biopsy of penis, deep (generally not applicable with HPV)

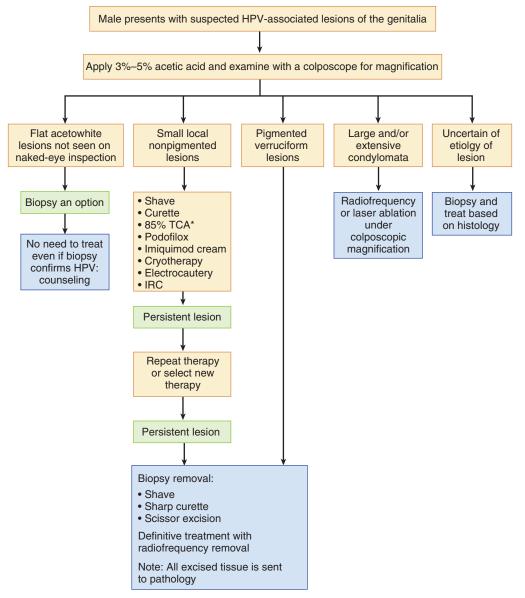

Figure 118-8 Summary of evaluation and treatment options for lesions of the male genitalia. HPV, human papillomavirus; IRC, infrared coagulation. \*Eighty-five percent trichloroacetic acid (TCA) is often a first choice for therapy. It is effective 70% of the time, is quick acting, and can treat extensive lesions during the office visit if they are not too large. It is inexpensive compared with other treatments; however, it does burn for 5 minutes after application. (Adapted from Pfenninger JL: Androscopy: Examination of the male patient. In Apgar BS, Brotzman GL, Spitzer M [eds]: Colposcopy: Principles and Practice. An Integrated Text and Atlas, 2nd ed. Philadelphia, Saunders, 2008, pp 483–496.)

# DORSAL SLIT FOR PHIMOSIS

Morteza Khodaee • Gary Yen

Although the exact definition of phimosis is still controversial, this condition has been recognized since ancient times. Phimosis can be physiologic, congenital, or acquired as a result of inflammation or infection. About 90% of boys have a fully retractable foreskin by the age of 3 years. American literature describes phimosis as scar formation of the foreskin secondary to any injury or inflammatory condition, with the inability to retract the foreskin over the glans penis (Wein and colleagues, 2007). Poor hygiene, diabetes, and zipper injuries are conditions that may increase the risk of phimosis. Acute phimosis may occur with infection or as a complication of various treatments for conditions such as verrucae, which can cause inflammation (e.g., 85% trichloroacetic acid, electrocoagulation).

Phimosis may lead to urinary retention or infection as well as *paraphimosis* (nonreducible retracted foreskin), which may require urgent or emergent intervention (Fig. 119-1). A debate exists over medical versus surgical management of phimosis. In countries in which circumcision is not widely practiced, nonsurgical and conservative surgical methods are often used. Recent worldwide studies demonstrated the efficacy of topical steroids (0.05% betamethasone cream once or twice a day for 4 to 6 weeks).

Surgical options for phimosis include dorsal slit, ventral slit, preputioplasty, and circumcision. Various preputioplasty techniques (including sutureless prepuceplasty, triple incision plasty, La Vega slit) have been developed to accomplish better cosmetic results. These techniques usually involve a longitudinal incision in an attempt to release the tight prepuce ring. Dorsal slit is a simple procedure involving a single cut along the dorsal foreskin that allows rapid access to the urethral meatus and glans penis.

#### **INDICATIONS**

- To gain emergency access to the urethral meatus for bladder catheterization in the presence of phimosis
- To prevent recurrent balanitis with abscess formation
- As an adjunct treatment before circumcision or after phimotic ring incision for paraphimosis

#### **CONTRAINDICATIONS**

- Active infection of the genitalia
- Anatomic abnormalities of the external genitalia (refer to urologist)

#### **EQUIPMENT**

- 10-mL syringe with 1-inch, 27-gauge needle
- 1% to 2% lidocaine without epinephrine
- Three small, straight hemostats
- Straight iris or small Metzenbaum scissors
- Suture scissors
- Absorbable suture (4-0) on small reversed cutting needle
- Needle driver
- Fenestrated drape

- Iodine solution or other antiseptic scrub
- Preparation bowl with  $4 \times 4$  gauze sponges
- Adson forceps

#### PREPROCEDURE PATIENT PREPARATION

Provide appropriate information to the patient about the procedure while obtaining informed consent (see the patient consent form online at www.expertconsult.com). Risks include pain, bleeding, infection, damage to the glans, poor cosmetic result, and hematoma formation. Benefits include resolution of phimosis, prevention of paraphimosis, increased ease of hygiene, decreased risk of urinary retention, and decreased pain with intercourse.

Place the patient in a comfortable supine position on an examination table in a well-lit room. Using sterile technique, surgically prepare the genital area with an antiseptic solution. Place the penis through a fenestrated drape and onto the surgical field.

#### **TECHNIQUE**

#### **A**nesthesia

- 1. Dorsal penile nerve block or modified "ring block" is used to obtain anesthesia after preparing and draping the penis (see Chapter 179, Subcutaneous Ring and Dorsal Penile Block for Newborn Circumcision). A dorsal penile nerve block anesthetizes the right and left dorsal nerves where they branch from the pudendal nerve from under the pubic bone. The lateral and ventral portions of the penile shaft are innervated by branches arcading from the dorsal midline, radiating toward the ventral surface. The axons innervating the glans are in a constant dorsal, midline location along most of the penile shaft.
- 2. A 27-gauge, 1-inch needle is inserted at the base of the penis just under the pubic bone and into Buck's fascia at the 2 o'clock and 10 o'clock positions (Fig. 119-2A and B).
- 3. After aspirating, inject 3 to 5 mL of lidocaine into the base of the penis at the 2 o'clock and 10 o'clock positions deep to Buck's fascia at the inferior edge of the pubic bone.
- Wait 5 minutes and test for the adequacy of anesthesia by grasping the dorsal foreskin with a hemostat.
- 5. A modified ring block can be used if anesthesia is incomplete. This is performed by interconnecting the two positions across the dorsal midline at the base of the penis in a subcutaneous fashion (Fig. 119-2C).

#### **Procedure**

- 1. After achieving local anesthesia, the operator grasps the distal dorsal foreskin in the 2 o'clock and 10 o'clock positions with two of the small, straight hemostats (Fig. 119-2D). Use the instruments to apply countertraction when performing the procedure.
- Identify the corona of the glans with the foreskin in a relaxed position or with just gentle straightening. The corona determines the proximal extent of the dorsal slit.

Figure 119-1 Paraphimosis.

- Gently retract the foreskin and attempt to identify the urethral meatus.
- 4. A closed small, straight hemostat is horizontally introduced into the opening of the foreskin between the inner layer of the foreskin and the glans penis. Advance it proximally to the coronal sulcus. Avoid entering the urethral meatus.

- 5. Tent up the foreskin and spread open the hemostat. Withdraw the instrument and twist to the right and left to break up adhesions around the circumference of the glans (Fig. 119-2E).
- 6. When lysis of adhesions is complete, the hemostat is withdrawn. Reinsert it open with one jaw of the hemostat in the plane between the glans and the inner layer of the foreskin while the other is placed on the outer skin. This should be at the 12 o'clock position with the instrument in a longitudinal position. Advance the instrument to the level of the coronal sulcus and clamp tightly. This crushes the interposed anesthetized foreskin. Leave in place for 3 to 5 minutes (Figs. 119-2F and 119-2G).
- 7. Remove the hemostat and cut the foreskin longitudinally with iris or Metzenbaum scissors along the entire distance of the serrated, crushed foreskin, being careful to leave 1 or 2 mm of crushed tissue at the apex lest uncrushed skin be incised, which can lead to significant bleeding.
- If crush hemostasis is inadequate or if the incision does extend too far and there is bleeding after cutting the dorsal slit, absorbable sutures should be used to obtain adequate hemostasis. This

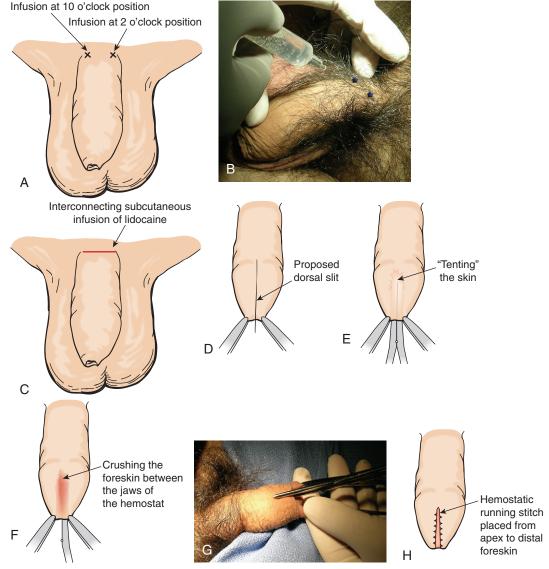

Figure 119-2 Dorsal penile nerve block. A and B, Inject at 10 and 2 o'clock positions. C, Partial ring block. D, Grasp foreskin at the 10 and 2 o'clock positions. Attempt to identify urethral meatus. E, Lysing adhesions. Separate the foreskin from the glans by spreading while withdrawing the hemostat. F and G, Place clamp longitudinally in the 12 o'clock position for 3 to 5 minutes. H, Placement of sutures to control bleeding if needed.

**Figure 119-3** "Dog-ear" appearance that results from the dorsal slit procedure. A formal, complete circumcision can be performed if desired and the inflammation has resolved. (From Roberts JR, Hedges JR [eds]: Clinical Procedures in Emergency Medicine, 5th ed. Philadelphia, Saunders, 2009.)

is performed by placing two running 4-0 Vicryl or Dexon sutures beginning at the apex of the dorsal slit and running distally to reapproximate the two layers of each side of the incision of the foreskin (Fig. 119-2H).

 Application of sterile petroleum jelly or antibiotic ointment on the wound edges prevents the dressing from adhering to the wound.

#### **COMPLICATIONS**

- Bleeding: Late bleeding can be controlled with direct pressure, Monsel's solution, Gelfoam, or the placement of hemostatic ligatures.
- Injury to the urethral meatus or glans: Avoid blind introduction of hemostat and scissors when performing the procedure to prevent injury to the urethral meatus or glans.
- Infection: Antibiotics can be used to control infection commonly due to skin pathogens such as Streptococcus or Staphylococcus.
- Pain: Hyperesthesia with intercourse may occur.
- Anesthesia complications: There may be hematoma formation at the site of injection.
- Poor cosmetic result: Elective circumcision may be recommended
  if the patient is not satisfied with the "dog-ear" appearance of the
  foreskin (Fig. 119-3).

#### POSTPROCEDURE PATIENT EDUCATION

- After successful dorsal slit for phimosis, the prepuce is easily retracted to access the urethral meatus and cleanse the glans penis.
- After completion of catheterization or cleansing, the foreskin should be reduced to avoid iatrogenic paraphimosis.
- Between 3 and 5 days of analgesics should be prescribed for postprocedure pain.
- The patient should wear loose briefs and gently cleanse the wound for 5 to 7 days with soap and water three to four times a day.
- The patient should avoid intercourse or masturbation for 4 to 6 weeks to prevent disruption of the wound.
- The patient should be instructed to return for postprocedure wound check in 1 to 2 weeks and to return immediately if excessive bleeding occurs.

 Instruct the patient on signs of infection that should not be confused with fibrinous exudate (a straw-colored exudate), which is part of normal healing.

#### **CONCLUSION**

Dorsal slit is an effective procedure that permits easy retraction of the foreskin, without the need for circumcision. It can be performed in the office setting or emergency department for complications related to phimosis.

#### **PATIENT EDUCATION GUIDES**

See the sample patient education and consent forms online at www. expertconsult.com.

# PROSTATE MASSAGE

Robert E. James • James R. Palleschi

Prostate massage has been used therapeutically and diagnostically in the management of recurrent or chronic prostatitis and prostatodynia. At this time, its primary benefit are to aid in the diagnosis of chronic prostatitis and for collecting a specimen of urine for a PCA3 (prostate cancer gene 3) test.

The urinary *PCA3* test has been found by some investigators to be helpful in screening for prostate cancer. After performing a prostate massage, the patient is asked to provide a urine specimen, which is sent to the lab to complete the *PCA3* analysis. The *PCA3* gene is overexpressed in patients with prostate cancer, but not in men with prostatitis or an enlarged prostate gland.

#### **INDICATIONS**

- Diagnosis of chronic or subacute prostatitis
- Management of prostatitis and prostatodynia (infrequent)

#### **CONTRAINDICATIONS**

- Acute prostatitis
- Prostatic abscess
- · Significant difficulty voiding

#### **EQUIPMENT**

- Examination glove and water-soluble lubricant
- Microscope
- Sterile culture container

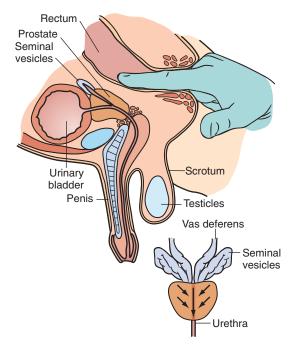

#### PREPROCEDURE PATIENT PREPARATION

Tell the patient that he may have an urge to urinate and may feel rectal pressure for 15 to 60 minutes after prostatic massage. Tell the patient to contact the physician or the nearest emergency department if he experiences chills, myalgia, rigors, or temperature above 101° F.

#### **TECHNIQUE**

- 1. Place the patient in a comfortable position for the prostate examination. A variety of positions may be used: the knee–chest position, left lateral decubitus position, or bent over the examination table. (With this position, the patient should place his elbows on the examination table and spread his heels apart. The patient is thus immobilized, which facilitates the prostate examination and the subsequent massage.) In addition, the patient may assist you in collecting the expressed prostatic fluid by holding the microscope slide below the urethral meatus of the glans penis.
- 2. Apply a generous amount of lubricant to the anus and to your gloved index finger. The examination will be more comfortable for the patient if he performs a mild Valsalva maneuver as the finger passes through and into the anal opening. In patients with

- a high-riding prostate, a Valsalva maneuver may bring the gland down to the examining finger.
- 3. For the prostate massage, press the pad of your index finger into the substance of the prostate. Start on the superior and lateral aspect of the prostate and move your index finger toward the midline or median sulcus. Gradually work from the base or superior aspect of the prostate gland down to the inferior portion or apex (Fig. 120-1). This motion is carried out several times bilaterally. Last, massage the median furrow, or mid-aspect, of the prostate gland, from the base to the apex. The prostatic secretions are massaged toward the prostatic urethra. These secretions then pass through the distal urethra and can be collected for microscopic examination and culture and sensitivity if desired. Normally, you need to repeat the prostatic massage for a period of 30 to 90 seconds before any secretions are obtained. The quantity collected may vary from a few drops to 2 to 3 mL. Some patients will not discharge any secretions (despite correct performance of the prostate massage as described) or may have discomfort sufficient to abort the procedure. Clinically, more than 15 white blood cells per high-power field suggest an infectious process.

**Figure 120-1** Technique of prostatic massage. The glandular substance is compressed from its lateral edges to the urethra, which lies in the center. The *arrows* in the inset drawing show the direction of pressure. The seminal vesicles are then stripped from above downward.

#### **COMPLICATIONS**

- Rarely, bacteremia or urosepsis may occur after a prostate massage.
  These problems can be avoided by not performing prostate
  massage on a patient suspected of having acute prostatitis or a
  prostate abscess.
- Occasionally, a patient with significant prostatism resulting from prostatic hypertrophy may develop prostatic edema after a massage, leading to temporary difficulty urinating or urinary retention
- Hematuria and hematospermia occur infrequently after a prostate massage.

**NOTE:** Any manipulation or trauma to the prostate gland may elevate a patient's serum prostate-specific antigen (PSA) for several weeks. Therefore, after performing a digital rectal examination, I would wait one week before performing a PSA and after a prostate massage, I would wait two weeks. An acute prostatitis or prostate infarct may cause an elevated PSA for up to six weeks.

#### **CPT/BILLING CODE**

87205 Prostatic smear

There is no CPT code for prostate massage.

#### **ICD-9-CM DIAGNOSTIC CODES**

- 600.0 Prostatitis, hypertrophic
- 600.9 Prostatitis
- 601.0 Prostatitis, acute
- 601.1 Prostatitis, subacute or chronic
- 601.3 Prostatocystitis
- 601.2 Abscess of prostate (note: avoid prostate massage)
- 601.9 Prostatitis (congestive)
- 602.1 Congestion or hemorrhage of prostate
- 602.9 Unspecified disorder of prostate, prostatodynia

# Prostate and Seminal Vesicle Ultrasonography and Biopsy

Philip J. Aliotta • Grant C. Fowler

Transrectal ultrasonography of the prostate (TRUSP) and seminal vesicles (SVs) is an essential tool in the assessment of these organs. Useful for defining anatomy, evaluating blood flow, and diagnosing and treating benign and malignant diseases of these glands, it is now the standard in most urologists' practices.

Although TRUSP-SV has proved helpful in the investigation of the infertile couple, more importantly, the introduction of TRUSP-SV has improved the accuracy of prostate tissue sampling. Even though a digital rectal examination (DRE)—guided fine-needle or core (e.g., Tru-Cut, Biopty) biopsy may confirm cancer, it is not as useful for excluding cancer; DRE is more helpful for guiding biopsy of a palpable nodule. TRUSP-SV improves the ability of the clinician to exclude cancer in more regions of the gland and has somewhat become the standard for evaluation of possible prostate cancer.

One important recent development for TRUSP-SV, especially for underserved areas, is that technicians or sonographers are now making services available on-site for primary care clinicians, even to guide biopsy. Overreading services for TRUSP-SV by a radiologist are also now available over the Internet (see the "Suppliers" section). This may revolutionize the management of suspected prostate cancer. However, an understanding of anatomy is necessary before scanning or biopsy. The prostate can be described by its general, vascular, zonal, tissue, or ultrasonographic anatomy.

Although recent large studies in the United States and Europe have failed to clarify whether men benefit from screening for prostate cancer, most organizations are now recommending at least a discussion of this topic with their clinician, especially in men younger than 75 years of age and with at least a 10-year life expectancy. A prostate biopsy may be indicated if the examination or laboratory result is suspect for cancer (Fig. 121-1). Although certain ethnic groups (e.g., African Americans) were thought to be at increased risk of prostate cancer in the past, more contemporary analyses suggest that this discrepancy is disappearing. Much of any remaining variation may be more strongly related to education, insurance status, and access to health care.

#### **GENERAL ANATOMY**

Figure 121-2 shows the general anatomy of the prostate and seminal vesicles.

#### **Prostate**

The prostate is a chestnut-shaped gland surrounded by a pseudocapsule of dense fibrous tissue and smooth muscle that connects with the muscular layers of the prostatic urethra. The pseudocapsule cannot be separated from the gland itself. It has an anterior, posterior, and lateral surface. The prostate base is contiguous with the bladder superiorly. The apex of the prostate is contiguous with the striated urethral sphincter. Lateral to the prostate is the pubococcygeal portion of the levator ani and endopelvic fascia. Denonvilliers' fascia, which separates the prostate from the rectum, is posterior to the prostate.

#### Vas Deferens and Seminal Vesicles

Arising from the tail of the epididymis, the vas deferens consists of a tortuous proximal portion and a dilated terminal portion called the *ampulla*. The ampulla is capable of storing sperm and lies posterior to the bladder. Bordering the base of the bladder, posteriorly, are the seminal vesicles. They also lie adjacent to the ampullae of the vasa deferentia and the distal ureters.

#### VASCULAR ANATOMY

The prostatic artery is a branch of the internal iliac artery. It divides into capsular and urethral arteries. The capsular arteries supply two thirds of the gland; the urethral arteries supply the remaining third. Branches of the inferior vesical artery supply the seminal vesicles, and occasionally the base of the prostate gland. The neurovascular bundles located posterolaterally (at the confluence of the seminal vesicle and prostate bilaterally) provide the main neurovascular supply and drainage system of the prostate.

#### ZONAL ANATOMY

Traditionally, the prostate was divided into five major lobes (anterior, middle, posterior, and two lateral lobes) and two minor lobes (trigonal and subcervical lobes). McNeal derived a three-dimensional model of the prostate, as illustrated in Figure 121-3.

#### **TISSUE ANATOMY**

The normal prostate consists of a combination of *glandular tissue* and *fibromuscular structures*.

#### Glandular Tissue

Glandular tissue accounts for about 66% of the prostate. There are four identified glandular zones, each with a distinct ductal system draining into a specific part of the urethra. The first three zones share similar histologic and embryologic origin. The fourth zone is the central zone (CZ) and differs histologically from the rest of the gland. It is derived from the Wolffian duct.

1. Peripheral zone (PZ; as much as 75% of the glandular tissue). The largest area of glandular tissue is in the PZ, which comprises the lateral and most of the posterior aspect of the prostate (except at the base). The PZ ducts drain into the distal urethral segment. The majority (>65%) of prostate cancers occur in the PZ.

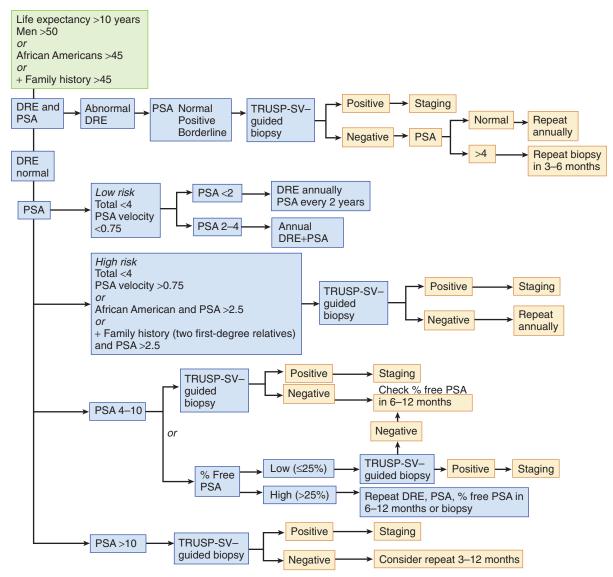

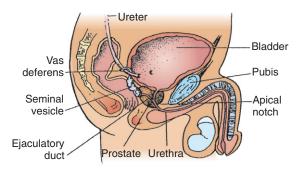

Figure 121-1 Sample algorithm for men who desire early cancer detection after discussion of pros and cons with their clinician. DRE, digital rectal examination; PSA, prostate-specific antigen; TRUSP-SV, transrectal ultrasonography of the prostate and seminal vesicles. Contemporary analyses of African American men suggest that ethnic discrepancies are disappearing. Much of any ethnic variation still noted may be more strongly related to education, insurance status, and access to health care rather than ethnicity. (Redrawn from Braunwald E, Fauci AS, Kasper DL, et al. [eds]: Harrison's Principles of Internal Medicine, 15th ed. New York, McGraw-Hill, 2001.)

**Figure 121-2** General anatomy of prostate and seminal vesicles. (From Brooks JD: Anatomy of the lower urinary tract and male genitalia. In Walsh PC, Retik AB, Vaughan ED Jr, Wein AJ [eds]: Campbell's Urology, 7th ed. Philadelphia, WB Saunders, 1998, pp 112–117.)

- 2. Transition zone (TZ; 5% or more of the glandular tissue). Between 5% and 10% of the glandular tissue is in the TZ. The TZ comprises two small lobules on either side of the proximal urethral segment just lateral to the periprostatic sphincter. The TZ is the origin of most symptomatic benign prostatic hyperplasia (BPH) and approximately 20% of carcinomas.
- 3. Periurethral glands (PUGs; 1% or more of the glandular tissue). These glands are embedded in the smooth muscle wall of the urethra, entirely within the preprostatic sphincter. Involved in the BPH process, these glands can give rise to an enlarged middle lobe.
- 4. Central zone (CZ; as much as 25% of the glandular tissue). The CZ is cone shaped and surrounds the ejaculatory ducts. The major distinction between the CZ and the PZ is that the CZ is relatively resistant to the development of cancer. Only 10% of cancers occur in the CZ. Interestingly, BPH does not seem to occur in the CZ.

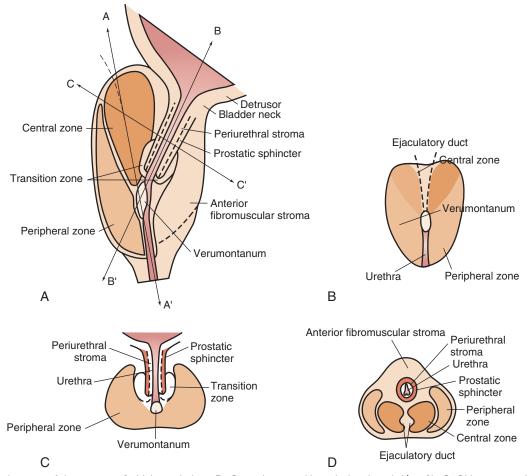

Figure 121-3 Anatomy of the prostate. **A,** Midsagittal plane. **B,** Coronal section (through the plane A-A' in **A)**. **C,** Oblique coronal section (through the plane B-B' in **A)**. **D,** Transverse section (through the plane C-C' in **A)**. (**A,** Redrawn from McNeal JE: Normal and pathologic anatomy of prostate. Urology 17[Suppl 3]:11–16, 1981. **B–D,** Redrawn from Muldoon LD, Resnick MI: Normal anatomy of the prostate. In Resnick MI [ed]: Prostatic Ultrasonography. Philadelphia, BC Decker, 1990.)

#### **Fibromuscular Structures**

Fibromuscular structures make up 33% of the prostate. There are four fibromuscular structures:

- 1. Anterior fibromuscular stroma (AFS)
  - A continuation of the detrusor muscle
  - Covers the anterior and anterolateral aspects of the glandular tissue from base to apex
- 2. Preprostatic sphincter (PPS)
  - Smooth muscle fibers of the lower ureters and superficial trigone
  - Intimately related to the TZ
  - Prevents pooling of urine in the proximal segment of the urethra
  - Prevents retrograde ejaculation
- 3. Postprostatic sphincter (POPS)
  - The proximal extension of the striated external urethral sphincter muscle covering the anterior and lateral aspects of the distal urethra
  - Contributes to continence
- 4. Longitudinal smooth muscle (LSM)
  - Part of the urethra

The key to understanding prostate tissue anatomy is to understand the anatomy of the prostatic urethra, which is approximately 3 cm long. It should be used as a primary reference point. After traveling through the proximal prostate, the urethra takes a 35-degree turn, angling anteriorly. The point of angulation divides the urethra into its proximal and distal urethral segments. The proximal urethral segment is related to two tiny glandular regions, the TZ and PUG, and to the preprostatic sphincter. The verumontanum lies entirely in the distal segment. In addition, the distal urethral segment is related to the function of ejaculation. The ejaculatory ducts and the excretory ducts (PZ and CZ) empty into the distal urethral segment.

#### **ULTRASONOGRAPHIC ANATOMY**

(For definitions of hyperechoic, isoechoic, and hypoechoic, see the "Interpretation" section.)

With ultrasonography, the anatomy is divided into two general areas that are immediately obvious to the examiner:

- 1. The outer area, or *outer gland*, is close to the rectum and generally described as isoechoic.
- 2. The inner area, or inner gland, is more hypoechoic in appearance.

#### Composition of the Inner and Outer Glands

#### Inner Gland

- Anterior fibromuscular stroma
- Preprostatic sphincter
- Periurethral glands
- Longitudinal smooth muscle
- Postprostatic sphincter

#### **Outer Gland**

- Transition zone
- Central zone
- Peripheral zone

#### **BASIC ULTRASOUND PHYSICS**

Ultrasound imaging is based on the "pulse echo" principle, whereby a short burst of ultrasound is emitted from a transducer and directed into the tissue. Echoes are produced as a result of the interaction of sound with tissue, and some of these echoes travel back to the transducer. By timing the period elapsed between the emission of the pulse and the reception of the echo, the distance between the transducer and the echo-producing structure can be calculated and an image produced (see Chapter 225, Emergency Department, Hospitalist, and Office Ultrasonography [Clinical Ultrasonography]).

Sound consists of longitudinal vibrations that propagate through a medium such as water or soft tissue. It consists of the repetitive (or periodic) production of such compressions, which travel in regular succession. The number of compressions produced each second is the *frequency* (measured in hertz [Hz]), and the distance between successive compressions, which depends on the speed at which the sound travels in the medium, is the *wavelength* (measured in millimeters). Tissues that are very elastic, dense, or compressible tend to transmit sound waves through them. Inelastic, less dense, or noncompressible tissues tend to reflect the sound waves.

Gain adjustment refers to the amount of amplification applied to a returning echo signal. Contrast and brightness adjustments can also be made to provide a homogeneous midrange echo pattern of the normal peripheral zone.

#### **Sound Frequency**

The characteristics of sound transmission are as follows:

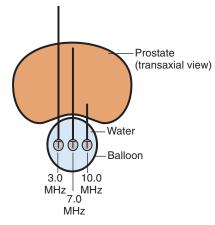

- The lower the frequency, the longer the wavelength.
- The higher the frequency, the shorter the wavelength.
- The lower the frequency of sound, the greater the ability to penetrate tissue, but the poorer the quality (resolution) of the ultrasonographic picture obtained.
- The higher the sound frequency, the poorer the tissue penetration by sound, but the better the quality (resolution) of the picture.

The ideal frequency for imaging the prostate is about 7 MHz. Although a 10-MHz probe provides better resolution of smaller objects, it has a more limited field of view; it shows only the part of the prostate closest to the rectum. A 3-MHz probe, with its lower frequency, delivers higher penetration, but the image quality and resolution usually suffer (Fig. 121-4).

#### **INDICATIONS**

#### **TRUSP-SV**

- Suspicion of prostatic abscess
- Azoospermia
- Brachytherapy
- Prostatitis
  - Acute
  - Chronic

**Figure 121-4** Ideal frequency for imaging the prostate is about 7 MHz. (From Cooner WH: Physical principles of prostate ultrasonography. Monogr Urol 11:18, 1990.)

- Chronic pelvic pain syndrome
- Prostatitis with an elevated prostate-specific antigen (PSA)
- Prostate volume study
- Detection of post-treatment prostate cancer recurrence
- Prostatic intraepithelial neoplasia on prior biopsy
- Prostate cancer staging
- Adenosis on prior biopsy

**NOTE:** In the patient with cancer, when attempting to determine the extent of local disease, TRUSP-SV is generally restricted to determining whether the tumor has invaded the seminal vesicles.

#### **TRUSP-SV and Prostate Biopsy**

- Evaluation of a palpable prostatic nodule or induration
- Abnormal PSA (Fig. 121-1 shows an algorithm combining PSA, free PSA, PSA velocity, and TRUSP-SV.)
  - Elevated PSA
  - $^{\circ}$  Low free PSA (<25%) in individual with PSA in the range of 4 to 10 ng/mL
  - Elevated PSA velocity (doubling in <6 months or >0.75 ng/ mL rise in PSA per year; optimally these have been done by same laboratory)
  - Elevated PSA density (>0.1 to 0.15 ng/mL)
- Detection of post-treatment prostate cancer recurrence
- Prostatic intraepithelial neoplasia on prior biopsy

#### **CONTRAINDICATIONS**

#### TRUSP-SV and Prostate Biopsy

- Bleeding disorders
- Anticoagulant therapy
- Significant rectal disease
  - Obstructing lesions
  - Fissures
  - Thrombosed hemorrhoids
  - Proctitis
- Untreated bacterial urinary tract infection
  - Cystitis
  - Prostatitis
- Operator not familiar with the procedure, the anatomy, or the interpretation of TRUSP-SV
- Patient life expectancy less than 10 years, or age 75 years or greater (relative contraindications)

**NOTE:** If a hypoechoic area is seen on transrectal ultrasonography (TRUSP-SV), it probably should be sampled for biopsy, regardless of PSA. Therefore, some experts warn against performing TRUSP

unless a biopsy is indicated; it should probably not be used for screening. The primary role of ultrasonography is to ensure accurate sampling of any lesions and of the entire gland during biopsy.

#### PREPROCEDURE PATIENT PREPARATION

- 1. Serum PSA on record
- 2. Documented DRE
- 3. Informed consent signed and copy on chart
- 4. Fleet enema 1 to 2 hours before the procedure
- 5. Fluoroquinolone therapy
  - The authors prefer a 3-day regimen using a quinolone the day before, the day of, and, if a biopsy is performed, the day after.
  - For patients undergoing repeat TRUSP-SV and biopsy (for persistent abnormalities in PSA despite negative biopsies and normal DRE), use a 5-day protocol of quinolone therapy, extending the quinolone for 3 days after the biopsy. Also, add metronidazole 500 mg twice a day by mouth for 3 days after the biopsy.
- 6. Patient vital signs before procedure
- 7. Patient positioning options
  - Knee–chest
  - Lithotomy
  - Left lateral decubitus with knees flexed 90 degrees (Fig. 121-5)

Indications, alternatives, risks, potential benefits, and expected results should be discussed with the patient and signed informed consent obtained. The patient should expect some discomfort with either TRUSP-SV or biopsy. He should also expect some discomfort with injection of the local anesthetic and the prostate biopsy. Let the patient know he will be warned before a biopsy. It will also be important for him to remain very still during certain portions of the procedure.

#### **EQUIPMENT**

An available assistant to help with the equipment is useful, especially if a biopsy is to be performed.

#### **TRUSP-SV**

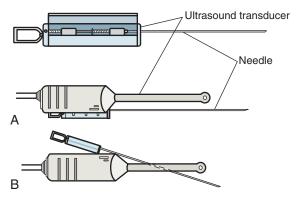

- Transducer sheath or condom (should be sterile if biopsy is to be performed)
- Nonsterile gloves (also sterile gloves if biopsy is to be performed)
- Ultrasonic gel
- Eye protection and gown (sterile gown if biopsy is to be performed)

#### Types of Prostate Ultrasonography

- Transabdominal
- Transperineal

Figure 121-5 Positioning of patient.

**Figure 121-6** Biopsy instrument can be introduced through an internal (A) or an external (B) needle guide or puncture guide. (Redrawn from Brackman J, Denis LJ: Prostate ultrasound and needle biopsy. In Graham SD Jr [ed]: Glenn's Urologic Surgery, 5th ed. Philadelphia, Lippincott-Raven, 1998.)

- Endourethral
- Transrectal (with and without color flow Doppler enhancement)

#### **Types of Transducer Design**

- Radial array (with cephalocaudad or right-to-left oscillation)
- Linear array (piezoelectric crystals are placed in a line, and each crystal fires and receives echoes in sequential order)

Recent advancements in ultrasound technology have resulted in the following:

- The development of biplanar probe transducers
- The development of a single probe to image the gland in both the transverse and sagittal planes
- A single probe that can have one of the following:
  - Two perpendicularly positioned transducers
  - A single transducer that can rotate
  - An end-fire transducer that can provide either a transverse or sagittal view by merely rotating the probe 90 degrees.

#### **Prostate Biopsy**

- Biopsy instrument, usually spring-loaded, and needle guide (Fig. 121-6)
- Sterile tray and sterile drapes for patient
- Bottles containing specimen preservative (formaldehyde)
- Lidocaine 1%, 22-gauge, 15- to 20-cm spinal needle and 10-mL syringe (optional)

#### **TECHNIQUE**

#### **TRUSP-SV**

#### **General Principles**

The performance of prostate ultrasonography requires the examiner to know which aspects of the procedure are operator dependent so that the best possible study can be obtained. No mandatory technical standards exist for performance of prostatic ultrasonography. The examination sequence remains a matter of personal preference. Practitioners should develop a technique that is thorough and reproducible and with which they are comfortable.

Prostate ultrasonography and examination should be carried out in at least two planes:

Transaxial-transverse (across the long axis). Images from this
orientation offer several advantages in the assessment of the
prostate:

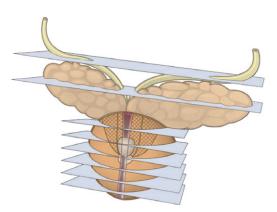

- Increased information about the lateral margins
- Assessment of capsular integrity
- Accurate volume assessment
- Longitudinal-sagittal (parallel to the body axis or long axis). Images from this orientation provide more information about the apex and base of the prostate and facilitate biopsy.

#### Procedure

- Perform a DRE before insertion of the probe. This procedure serves many purposes:
  - Dilates the anal sphincter, reducing discomfort from probe insertion.
  - Assesses the gland for size, shape, and areas of irregularity or suspicion. This enables the sonographer to associate palpable lesions with what is being viewed during the study.
  - Rules out a rectal obstructive process of either benign or malignant etiology.
- 2. Position the patient. Various positions will work, but the left lateral decubitus position is often more comfortable for the patient and may reduce bowel gas interference (see Fig. 121-5).
- 3. Prepare the probe. A small amount of ultrasonic gel is placed either in the tip of the probe sheath or on the tip of the probe. The cover is then inserted over the probe. Any air bubbles over the tip of the probe should be smoothed away.
- Have the patient perform a slight Valsalva maneuver during probe insertion to relax the sphincter and further facilitate probe insertion.
- 5. After insertion, while scanning in the transaxial mode, advance the probe to the level of the seminal vesicles. Making parallel images (cuts), scan from superior to inferior (Fig. 121-7). Examination of the seminal vesicles should focus on the following:
  - Symmetry
  - Size
  - Echo pattern
  - Any masses
  - Cystic changes

Because the seminal vesicles do not always lie symmetrically in the body, it is occasionally difficult to comment on their symmetry on a cut-by-cut basis. Often they must be studied and their images interpreted as they appear in their entirety. If prostate cancer is present, it is important to determine whether there has been local invasion to the seminal vesicles (see "Interpretation" section).

6. From the seminal vesicles, the probe is withdrawn to the level of the base of the prostate and all areas from the base to the apex

**Figure 121-7** Ultrasonographic transaxial examination of the seminal vesicles and prostate using parallel images from superior to inferior. (From Rifkin MD: Ultrasound of the Prostate: Imaging in the Diagnosis and Therapy of Prostatic Disease, 2nd ed. Philadelphia, Lippincott-Raven, 1997.)

- should be scanned. Evaluate the prostate for symmetry, its lateral margins, and the integrity of the capsule. Assess the inner and outer gland for irregularities. The periprostatic "environment" is also assessed at this time. Normal peripheral zone echogenicity represents the *baseline* or is *isoechoic*. Any lesion that is less echogenic is labeled *hypoechoic*; anything giving rise to more echoes is *hyperechoic*.
- 7. The probe should then be rotated (or a perpendicular plane in the probe activated) to scan the prostate longitudinally. The clinician should be thorough and evaluate the entire prostate and surrounding tissue in each longitudinal plane. Particular emphasis should be placed on scanning and evaluating the apex and base of the prostate.
- 8. Volume determination should be performed. Various software applications or technical features of individual ultrasound machines enable the examiner to estimate prostate volume. An option is a formula for calculating estimated prostate volume: prostate volume (mL) = (π/6) × (anterior-posterior diameter [cm]) × (transverse diameter [cm]) × (sagittal diameter [cm]). Regardless of technique used, the error in measuring prostate volume may approach 25%.

**SPECIAL CASE:** Ultrasonography and/or biopsy of a man without a rectum: this requires transperineal ultrasonography in conjunction with magnetic resonance imaging (MRI). The MRI defines the areas of suspicion as a region of low signal intensity on T2-weighted sequences. Although transperineal ultrasonography may help localize the abnormal area of the prostate, it seldom demonstrates the specific lesion. The transperineal approach to biopsy is more painful but carries a lower risk of infection than the transrectal approach.

#### **Prostate Biopsy**

- 1. With eye protection in place, the clinician is gowned in a sterile manner and the patient draped likewise. A small amount of ultrasonic gel should be placed either on the tip of the probe sheath or on the tip of the probe. The needle guide and transducer are then covered with the sterile sheath. The sterile sheath often has an extension that can be unrolled over the transducer cord. Any air bubbles located over the probe tip should be smoothed away.
- 2. After having the patient perform a slight Valsalva maneuver, the probe is inserted in the same manner as for TRUSP-SV.
- 3. Prostate anesthetic block: It is the authors' opinion that providing a local anesthetic block with 1% lidocaine before prostate biopsy is beneficial. It may not only reduce anxiety and discomfort, but it may enhance patient compliance (especially if a repeat biopsy is ever necessary). After the probe is in the rectum, a 22-gauge, 15- to 20-cm spinal needle is introduced through the needle guide on the probe. The needle is then advanced into Denonvilliers' fascia and the area adjacent to the apex in the longitudinal plane. Lidocaine is injected between the gland and the rectum. The authors usually inject 4 mL of local anesthetic in the apical region and then switch to the horizontal plane to inject the remaining 3 mL into the right and left neurovascular bundles. After waiting 5 to 10 minutes for the anesthetic to take effect, one can proceed with the biopsy. At this point, some clinicians also use moderate (conscious) sedation (see Chapter 2, Procedural Sedation and Analgesia).
- 4. The biopsy instrument, usually a spring-loaded biopsy gun, is then inserted until the tip of the instrument can be seen at the edge of the prostate. For an outer gland lesion, the tip of the instrument is placed just in front of the lesion, at the edge of the mass and before the prostatic capsule is penetrated. For an inner gland lesion, the tip of the instrument must first penetrate the capsule and outer gland before it is placed just in front of the lesion, at the edge of the mass.

**Figure 121-8** Echogenic patterns of the prostate. **A,** Isoechoic patterns. The images are typically produced by the glandular areas of the prostate and appear as low-level gray. The images are in a midrange and a medium percentage of sound waves are reflected back to the transducer. **B,** Hypoechoic patterns (*arrow*) are seen typically in the fibrous and muscular structures of the prostate and with cancers of the prostate. With hypoechoic patterns, fewer echoes are reflected back and more actually pass through the tissues, making them appear darker. **C,** Hyperechoic patterns (*arrows*) result when more sound waves are reflected back to the transducer, producing images that are light gray to white. The periprostatic fat is hyperechoic, as are some cancers. (From Rifkin MD: Ultrasound of the Prostate: Imaging in the Diagnosis and Therapy of Prostatic Disease, 2nd ed. Philadelphia, Lippincott-Raven, 1997.)

- If the patient is awake, to avoid any surprises, he should be warned just before the instrument is fired. The instrument is then fired. Any additional suspect areas on TRUSP-SV should likewise be sampled.
- 6. Additional random passes are then made, obtaining biopsies in the superior, central, and inferior portions of the prostate. Emphasis should be placed on obtaining tissue from the peripheral zone. The specific number of biopsies varies by clinician, but the current literature recommends 12 to 18 passes (6 to 9 on each side). Various systems are used to label the biopsies, with "1" or "A" commonly used to label the right superior gland, "2" or "B" for right middle, "3" or "C" for right inferior (apex), "4" or "D" for left superior, "5" or "E" for left middle, and "6" or "F" for left inferior. When in doubt about which system to use, the clinician can merely be descriptive with the labeling (e.g., "right superior").

# INTERPRETATION AND EVALUATION OF THE PROSTATE

#### Interpretation

From the prostate, three types of echogenic pattern are described: isoechoic (Fig. 121-8A), hypoechoic (Fig. 121-8B), and hyperechoic (Fig. 121-8C). Unfortunately, no single finding on ultrasonography permits universal distinction between malignant and benign conditions. However, most cancers are hypoechoic. Cancers less than 5 to 7 mm, those that are well differentiated, and those located in the TZ are difficult to distinguish from normal prostate.

#### **Evaluation**

- General appearance
- Inner gland status
- Outer gland status
- Anterior prostate status
- Any focal intraprostatic abnormalities
- Status of the internal architecture
  - Normal
  - Disrupted
- Integrity of capsule
- Urethral position
- Focal lesion(s)
  - Number
  - Location
  - Echogenic pattern: hypoechoic, isoechoic, hyperechoic, mixed, anechoic
  - Margin of the focus: well defined, poorly defined

- Calculi
- Cvsts
- Ejaculatory duct status
  - Normal
  - Dilated
  - Infiltrated
- Neurovascular bundles present?
- Lymph nodes visible?
- Seminal vesicles
  - Overall, symmetric or asymmetric
  - Size
  - Shape
  - Echo pattern
  - Cystic changes
  - Solid mass effect
- Rectal wall integrity

# Normal Ultrasonographic Appearance of the Prostate Gland\*

- The peripheral zone is isoechoic and the transitional zone hypoechoic.
- The appearances change with enlargement—the peripheral zone becomes thinner.
- The gland shape depends on the type of TRUSP-SV probe used.
- The central zone is not identifiable as a separate area.
- The prostatic capsule, although seen, is not a true capsule.
- Flow on color Doppler is symmetric.

# Abnormal Ultrasonographic Appearance of the Prostate Gland

Most prostate cancers appear as a hypoechoic lesion in the peripheral zone.

#### Hints for Staging

- Findings consistent with extracapsular extension of prostate cancer include bulging of the prostate contour and an angulated appearance of the lateral margin.
- Findings consistent with seminal vesicle invasion include a posterior bulge of the prostate contour at the base of the seminal vesicle and asymmetry of echogenicity in the seminal vesicles associated with hypoechoic areas at the base of the prostate.

<sup>\*</sup>Patel and Rickards, 2002.

#### **COMPLICATIONS**

#### **TRUSP-SV** and **Prostate Biopsy**

- Rectal bleeding from the following:
  - Hemorrhoidal vessels
  - Rectal wall laceration
  - Arteriovenous malformation
- Hematuria
- Hematospermia
- Urinary retention
- Urosepsis
- Bacteremia
- Vasovagal response with or without seizure

#### Prostate Biopsy (Rare)

- Perirectal or pelvic hematoma or hemorrhage
- Needle tract seeding of cancer

#### POSTPROCEDURE PATIENT EDUCATION

Postprocedure vital signs should be performed and fluids offered or provided (e.g., sport drink, fruit juice). The TRUSP-SV findings and any instructions should be reviewed with the patient. A follow-up appointment should be made. If biopsies were performed, the results will be discussed with the patient at the follow-up appointment. Patients should be aware that even with a negative biopsy, they may have microscopic cancer in a small area of the prostate. If the biopsy was for an abnormal PSA and it remains abnormal, a repeat biopsy may be necessary at a later date. After TRUSP-SV or biopsy, the patient should call the facility for difficulty urinating, rectal bleeding, high fever, or further questions.

# SELF-INJECTION THERAPY FOR THE TREATMENT OF ERECTILE DYSFUNCTION

Robert E. James • James R. Palleschi

Significant advances have been made in the diagnosis and treatment of erectile dysfunction. Although the introduction of oral drugs has decreased the need for and the use of injection therapy, it is still indicated in some patients. The self-injection of vasoactive agents into the corpora cavernosa now enables many patients to resume satisfactory sexual activities without surgery.

Oral medications (sildenafil, tadalafil, and vardenafil) are most effective in patients with mild to moderate impotence. This category would include men who are able to obtain a good erection but cannot maintain it and those men who have an erection that is at least a 5 out of 10 in rigidity, where "10" is defined as the best erection they can remember.

The *transurethral form of alprostadil* (MUSE) is most effective in men who have difficulty maintaining an erection and in those who have a partial erection, or 5 out of 10 in rigidity.

Despite the advances in the treatment of erectile dysfunction, vacuum erection devices remain an option or adjunct. These devices are attractive to patients who have failed oral therapy and decline or fail intraurethral or intracavernosal alprostadil. Patients using intracavernosal therapy who want to have intercourse more than three times a week usually meet their goal by using vacuum erection devices (see Chapter 125, Vacuum Devices for Erectile Dysfunction).

In the treatment of moderate to severe erectile dysfunction, intracavernosal therapy with vasoactive agents still has a very important role.

In July of 1995, the U.S. Food and Drug Administration (FDA) approved *injectable alprostadil* (prostaglandin  $E_1$  [PGE<sub>1</sub>]) for the treatment of organic erectile dysfunction. The American Urological Association's guidelines for the treatment of erectile dysfunction recommend alprostadil as the drug of choice, and it is the only intracavernosal vasoactive agent approved by the FDA.

There is also *papaverine hydrochloride*, a nonspecific smooth muscle relaxant. In addition to alprostadil, which is a vasodilator and a smooth muscle relaxant, papaverine hydrochloride may be used with *phentolamine mesylate*, a smooth muscle relaxant that enhances the effect of papaverine. For several years these agents have been used extensively for impotence, although this remains an unlabeled indication.

These vasoactive agents induce an erection by increasing arterial blood flow, relaxing the sinusoidal spaces within the cavernosal tissue, and increasing venous resistance. An excellent erection that lasts for 30 to 90 minutes usually occurs in patients with mild to moderate arterial insufficiency, mild to moderate venous incompetence, psychogenic impotence, neurogenic impotence, and medication-induced impotence.

#### **INDICATIONS**

- Impotence resulting from arterial insufficiency.
- Impotence resulting from mild to moderate venous incompetence.
- Psychogenic impotence. (Patients with performance anxiety may be treated with counseling, oral agents, short-term intracavernosal agents, or a combination of these methods.)
- Neurogenic impotence.
- Medication-induced impotence, when drug therapy cannot be altered or terminated.
- Diagnostic erection.
- Intolerance to or ineffective oral drugs.

#### **CONTRAINDICATIONS**

- Blood dyscrasia, coagulation disorder, or anticoagulation drug therapy
- Unstable cardiovascular disease
- Impaired manual dexterity or vision
- Presence of a prosthetic penile device
- Valvular heart disease
- Intolerance to the test dose of the vasoactive agent
- Patients taking monoamine oxidase (MAO) inhibitors
- Patients with a propensity toward secondary forms of priapism, such as individuals with sickle cell disease or trait, leukemia, and multiple myeloma

**NOTE:** If a physician elects to use intracavernosal pharmacotherapy to treat erectile dysfunction in men with Peyronie's disease, a special informed consent is advised.

#### **EQUIPMENT**

- 1- to 3-mL syringes with ½-inch, 27- and 30-gauge needles
- Alcohol swabs
- Vasoactive agents
  - Papaverine HCl 30 mg/mL is available in 10-mL multidose vials.
  - Papaverine and phentolamine solution: Inject 5 mg (or 10 mg) of phentolamine (Regitine; Novartis, East Hanover, NJ) into a 100-mL vial of papaverine 30 mg/mL. The (approximate) concentrations will be papaverine 30 mg/mL and phentolamine 0.5 or 1.0 mg/mL.
  - PGE<sub>1</sub> (alprostadil): There are two proprietary forms of injectable alprostadil for the treatment of erectile dysfunction available in the United States: Caverject and Edex (Schwarz Pharma, Mequon, Wis). The clinical dose range varies from 2

- to 40  $\mu g$  per injection. Each manufacturer has provided alprostadil in a ready-to-use, easily assembled syringe that does not require refrigeration. The syringes are meant for single use only.
- PGE<sub>1</sub> (alprostadil) is also available in 1-mL ampules from Upjohn (Kalamazoo, Mich) as Prostin VR Pediatric 500 mg/ mL. For the desired concentration, inject 0.2 mL of this preparation into each of five 10-mL vials of bacteriostatic normal saline for injection. Each vial will contain PGE<sub>1</sub> 10 mg/mL.

Bennett and coworkers in 1991 developed a trimix combination therapy for the treatment of erectile dysfunction. This three-drug mixture contains 2.5 mL of papaverine (30 mg/mL), 0.5 mL of phentolamine (5 mg/mL), and 0.05 mL of alprostadil (500  $\mu$ g/mL) for intracavernous injection. Most patients require less than 0.25 mL per injection.

Open vials or compounded solutions should be refrigerated to maintain sterility and effectiveness. A 30-day expiration date is recommended; however, sufficient effectiveness has been reported for up to 3 months.

 $\alpha$ -Adrenergic agents will cause vasoconstriction and thus will usually result in prompt detumescence should priapism occur. Some of the available agents include *ephedrine sulfate*, *epinephrine*, and *phenylephrine hydrochloride* (Neo-Synephrine). (See the "Treatment of the Persistent Erection [Priapism]" section for dilutions and use.)

#### PREPROCEDURE PATIENT PREPARATION

Discuss the self-injection program, alternatives, and potential complications with the patient and, when possible, his partner. Patients using this program may experience bruising at the injection site and local or systemic infection (<0.05% incidence). Chronic fibrosis at the injection site may occur with repeated injections, and this may result in pain or penile curvature. Papaverine may elevate the results of liver function tests. Consequently, patients should obtain pretreatment liver function tests and should be retested every 3 months while using papaverine. If the liver function test values begin to rise, the medication should be discontinued. If the initial liver function test results are elevated, use PGE<sub>1</sub> instead of papaverine. Approximately 20% of patients using PGE<sub>1</sub> may experience an ache in the penis that may last for several hours and that may recur with each injection. Priapism, an erection lasting longer than 4 hours, may occur in up to 10% of patients receiving any of the vasoactive agents, but it reportedly occurs less frequently with PGE<sub>1</sub>. Systemic side effects, such as dizziness and orthostatic hypotension, occur in 2% of patients receiving these vasoactive agents and are believed to be secondary to penile venous incompetence.

Instruct the patient to contact the physician if he experiences a significant erection that persists for more than 4 hours. This condition will need to be treated promptly to prevent intracorporeal fibrosis and failure to respond to future therapy.

#### **TECHNIQUE**

- 1. Complete the patient's history and physical examination to provide a preliminary diagnosis.
- 2. Select the agent and the dose. If psychogenic or neurogenic impotence is suspected, use a smaller dose of the vasoactive agent. In patients with psychogenic impotence, one fourth of the maximum dose should be used; in patients with neurogenic impotence, no more than one sixth of the maximum dose should be used initially. The maximum dose of papaverine is 60 mg, and that of PGE<sub>1</sub> is 20 μg. To reduce the risk of priapism and to prevent other untoward reactions, even when vascular disease is suspected as the cause of impotence, the initial dose should not exceed 30 mg of papaverine or 10 μg of PGE<sub>1</sub>. If a satisfactory erection does not occur, the dose may be appropriately increased at the time of the next office appointment. Although the usual

- dose of *alprostadil* is between 10 and 20  $\mu g$ , urologists have used up to 40  $\mu g$  in some cases. In patients with psychogenic or neurogenic impotence, you should begin with 2 to 5  $\mu g$  and gradually increase the dose as needed. Otherwise, the usual starting dose is 10  $\mu g$ .
- 3. Once the desired dose of the vasoactive agent has been selected, extend the patient's penis and prepare the lateral surface with an alcohol swab. Locate the neurovascular bundle at the 12 o'clock position and the urethra at the 6 o'clock position (Figs. 122-1 and 122-2). Select as the injection site an area between these two structures (1 to 5 o'clock on the patient's left, 7 to 11 o'clock on the patient's right) in which there are no superficial veins. The injection site may be anywhere between the base of the penis and just proximal to the glans penis. It is strongly recommended that only Caverject or Edex be used. With the patient standing, gently direct the penis to the left or the right to expose its lateral surface. Introduce a 27- or 30-gauge needle perpendicular to the skin and tunica albuginea and into the corpus cavernosum. Normally, the needle is advanced 0.5 inch. Inject the vasoactive agent rapidly as a bolus into the corpus cavernosum. The medication will enter the opposite corpus cavernosum through cross-circulation. If resistance is met as the medication is injected, withdraw the needle slowly as you continue to inject. The resistance normally occurs because the needle is against the opposite wall of the corpus cavernosum. To prevent injection of the medication into the subcutaneous space, advance the needle the entire 0.5 inch and then withdraw slowly.
- 4. Once the injection is completed, have the patient apply pressure to the injection site for 2 minutes.
- 5. Evaluate the condition of the patient periodically during the first 15 minutes after the injection. The patient's comfort, presence of side effects, and the quality of the erection should be evaluated at 15-minute intervals for 30 to 60 minutes. To evaluate the quality of the erection the patient will experience with sexual stimulation, you may ask the patient to apply manual stimulation. The patient may be discharged from the office within 30 to 60 minutes after the injection, provided he is comfortable and not experiencing any side effects. Instruct the patient to contact you if priapism occurs. Once the appropriate dose has been determined and the patient is skilled and comfortable with self-injection therapy, he may perform it independently, but no more than three times per week. Priapism rarely occurs after the appropriate dose has been determined, unless the patient independently increases the dose.

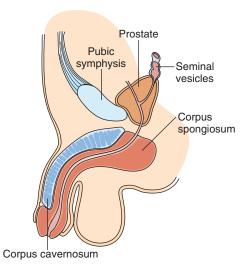

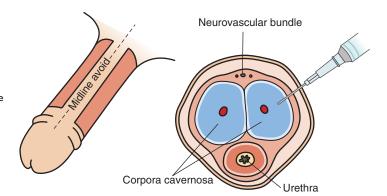

Figure 122-1 Side view of penis and scrotum.

**Figure 122-2** Intracavernous injection site. The clinician grasps the glans and pulls firmly outward to tense penis without rotating.

# Treatment of the Persistent Erection (Priapism)

If the patient does not have significant hypertension or unstable cardiac or cerebrovascular disease, an intracavernosal  $\alpha$ -adrenergic agonist is safe and very effective in the treatment of priapism. Priapism is defined as an erection that lasts over 4 hours. Before injecting the antidote, you should attempt to treat the priapism by first irrigating blood from the corpus cavernosum with saline. Inject the skin over the aspiration site (shaft of the penis) with 0.5 to 1 mL of local anesthetic (1% to 2% lidocaine). If ineffective, the patient may benefit from a penile block with 1% to 2% lidocaine and intravenous morphine sulfate. Then irrigate using aseptic technique with a 30-mL syringe and a 16- to 18-gauge needle. Insert the needle 0.5 inch into the midlateral corporal body and irrigate with saline. If the priapism does not resolve with irrigating with 250 to 500 mL of saline, proceed with injection of ephedrine, epinephrine, or phenylephrine, as discussed in the following section.

The following agents may be considered for the treatment of priapism if aspiration and irrigation of blood are unsuccessful:

- Ephedrine sulfate: A vial contains 50 mg (25 mg/mL). Initially inject 10 to 25 mg into the corpus cavernosum. If detumescence does not begin within 15 to 30 minutes, the dose may be repeated. A maximum of 50 mg may be given. Ephedrine is the drug of choice because of its efficacy, simplicity, and safety. If ineffective, a urology consult is advised.
- Epinephrine: Inject 1 mL of diluted epinephrine (10 to 20 μg/mL) slowly into the corpus cavernosum every 5 to 10 minutes. This may be repeated twice, and if satisfactory detumescence does not occur, a urology consultation should be obtained. (To prepare the proper dilution, use epinephrine 1:10,000 solution. For 10 μg/mL, dilute 0.1 mL of epinephrine with 0.9 mL of normal saline. For 20 μg/mL, dilute 0.2 mL of epinephrine with 0.8 mL of normal saline.)
- Phenylephrine hydrochloride (Neo-Synephrine) 1%: Inject 1 mL slowly into the corpus cavernosum every 5 to 10 minutes. If satisfactory detumescence does not occur after the second dose, a urology consultation should be obtained. (To prepare the proper dilution, use phenylephrine hydrochloride 0.1 mL diluted with 0.9 mL of normal saline for 100 μg/mL. Use phenylephrine hydrochloride 0.2 mL diluted with 0.8 mL of normal saline for 200 μg/mL.)

These medications should be given individually and never in combination. Monitor the blood pressure and pulse closely in all patients. Cardiac arrhythmias and significant hypertension may occur. If these measures are ineffective, obtain a urology consultation. Surgical intervention may be required at this time.

#### **COMPLICATIONS**

- Priapism (an erection that lasts over 4 hours)
- Infection
- Subcutaneous ecchymosis or hematoma
- Fibrosis to the corpus cavernosum with repeated injections
- Curvature of the penis occurring after repeated injections
- Painful erections
- Dizziness or postural hypotension
- Myocardial infarction, stroke, or both, in patients with unstable cardiac or cerebrovascular disease
- Elevated liver function test results (papaverine)

#### POSTPROCEDURE PATIENT EDUCATION

As many as 50% of men using self-injection therapy will discontinue this treatment within 1 year. There may be many reasons for this cessation, including lack of a suitable partner; fear of needles; inadequate response to therapy; fear of complications; lack of sexual spontaneity; and the desire for alternative therapy, including a permanent solution, such as a penile prosthesis. Consequently, the patient should be seen periodically and should be asked about his sexual activity and satisfaction with self-injection therapy.

#### **PATIENT EDUCATION GUIDES**

## SPERM BANKING

Dan B. French • Edmund S. Sabanegh, Jr.

Men undergoing some types of medical therapy such as chemotherapy, radiation therapy, or surgery face the real possibility of temporary or permanent infertility. An option to preserve fertility potential is to freeze (cryopreserve) sperm before undergoing these other medical treatments. Cryopreservation of sperm, or sperm banking, involves the freezing of sperm in liquid nitrogen followed by long-term storage for future use. Unfortunately, patients who may benefit from cryopreservation of sperm are not always aware of their options or may not even be considering their future fertility, considering the stress of their present situation. Therefore, a well-informed health care provider who is able to appropriately discuss cryopreservation with the patient is an invaluable resource.

Cryopreserved sperm was first used to achieve successful pregnancy in 1953. Because of moral controversy surrounding assisted reproductive techniques at the time, it would be another 10 years before use of cryopreserved sperm for artificial insemination would gain popularity. A technique using liquid nitrogen for freezing of sperm was developed in 1963. Over the years, other technical developments, such as the addition of cryoprotectants and the advancement of assisted reproductive techniques, have been introduced. With the advent of in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI), even men with very few, poor-quality sperm can achieve fertility, with pregnancy rates approaching 50% per cycle.

#### **INDICATIONS**

One of the most important patient populations that may need this service is reproductive-age men who will undergo gonadotoxic chemotherapy for malignancy. Testicular cancer, leukemia, and lymphoma are the most common malignancies that may have reproductive consequences, either from the treatment or the disease itself. Cytotoxic chemotherapeutic regimens often result in acute azoospermia as defined by the absence of sperm in the ejaculate. Depending on the regimen used, only half of these men will recover spermatogenesis, and there is no precise way to predict who will do so. Even before receiving any cytotoxic therapy, these patients often have suboptimal semen quality as a result of their systemic disease, and therefore every effort should be made to cryopreserve any sperm they might have before initiating chemotherapy.

Radiation therapy, often used for certain testicular tumors and Hodgkin's disease, is also gonadotoxic, and appropriate individuals should be offered sperm cryopreservation before treatment. Even if the radiation is administered to distant sites and the testes are shielded, fertility can be impaired owing to scatter radiation.

Nonmalignant conditions may also require gonadotoxic treatment. Conditions such as autoimmune disorders, inflammatory bowel disease, or organ transplants may require immunosuppressive or cytotoxic therapies that impair fertility. These patients should be offered sperm banking if it is known that their treatment may lead to infertility.

Because up to 5% of men receiving a vasectomy will eventually request a restoration of their fertility, it is reasonable to offer sperm banking before vasectomy. Men who are undergoing vasectomy reversal may choose to have sperm extracted at the time of reconstructive surgery in the event that the reconstruction fails in the future.

Men with a history of spinal cord injury may require electroejaculation or surgical extraction for sperm retrieval. They may also choose to have sperm banked as a matter of convenience instead of undergoing repeated procedures.

#### **CONTRAINDICATIONS**

The main contraindication to sperm cryopreservation is the *presence* of a disease communicable through the sperm. For this reason, donors are screened for human immunodeficiency virus, hepatitis B and C, chlamydia, gonorrhea, syphilis, cytomegalovirus, and human T-lymphotropic virus. Specimens are incubated for 6 months to confirm absence of any of these conditions before use.

Although not a contraindication, it should be noted that sperm with damaged DNA do not thaw as well as healthy sperm. With the development of IVF/ICSI, even semen samples with elevated levels of sperm DNA damage or severe oligospermia can be used effectively. Among the thousands of conceptions that have occurred from frozen sperm, the incidence of birth defects has been no different than that among children conceived through intercourse.

#### **PROCEDURE**

The patient will complete various forms, including a *consent form*, agreement of fee schedules, and, most important, a legal document clearly outlining the fate of the sperm should the patient die or otherwise become incapacitated. Blood samples are drawn for screening for various sexually transmitted infections. Before freezing, a semen analysis is performed to assess the concentration, total number, and quality of sperm. The sample is then mixed with cryoprotectants such as egg yolk or glycerol.

Sperm can be collected for banking from various sources, depending on the clinical circumstances. These include ejaculated semen specimens, sperm recovered from the bladder in patients with retrograde ejaculation, and surgically retrieved specimens from either the epididymis or testicular tissue. If the specimen is an ejaculate, it should be produced by masturbation at the collection site or at least brought to the collection site immediately after collection. The donor should not have had any ejaculations within the preceding 48 to 72 hours if at all possible. Depending on semen quality, several collections separated by 48 to 72 hours of abstinence may be required. Once collected, the sample is allowed to liquefy at room temperature.

The specimen is labeled with the pertinent data, including but not limited to patient name, identification number, and date of collection. This information is verified by the donor. Sometimes photographs of the donor are used as an additional security feature. The sample is divided into a certain number of straws or vials for freezing based on the concentration of sperm. One of these aliquots is thawed the next day to assess for viability following thaw. This test is used as a predictor of future viability for the entire batch. Samples, once preserved, can be stored for many years without fear of deterioration.

The cost of sperm cryopreservation varies between institutions. Cost for an initial analysis and freezing ranges from \$150 to \$600. This price is even higher when specimens must be shipped, usually when using a commercial cryobank. Most cryobanks assess annual storage fees ranging from \$50 to \$365.

#### **CONCLUSION**

The incidence of cancer in reproductive-age men has been increasing worldwide over the past 25 years. Although cancer cure and the management of acute toxicities remain the paramount issues for both the medical professional and the patient, future fertility is a major concern for young patients. With advances in both cryopreservation technology and assisted reproductive techniques, cryopreservation of sperm has become a valuable tool in the treatment of male infertility. Men of reproductive age embarking on gonadotoxic treatments for cancer as well as other selected groups of patients need to be aware that cryopreservation of sperm is an option, and it is incumbent on the provider to educate them about this option. The procedure is relatively simple and affordable and, unfortunately, remains underutilized.

# IMPLANTABLE HORMONE PELLETS FOR TESTOSTERONE DEFICIENCY IN ADULT MEN

John Harlan Haynes III • Terrance S. Hines

Testosterone is responsible for normal growth and development of male sex organs and maintenance of secondary sex characteristics. As the primary androgenic hormone, its production and secretion are the end products of hormonal and biochemical interactions. Gonadotropin-releasing hormone (GnRH) is secreted by the hypothalamus and controls the pituitary secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH regulates production of testosterone by the testes, and FSH stimulates spermatogenesis. Testosterone can be converted in the body either to dihydrotestosterone by 5- $\alpha$  reductase or to estradiol by aromatase. Dihydrotestosterone preferentially binds to androgen receptors and becomes the more active form involved in hair growth and sebum production. Estradiol may be important in maintaining libido and bone mass, but may contribute to truncal obesity and feminine characteristics.

Testosterone deficiency is common, occurring in 1 in 200 men. The prevalence increases with age as testosterone levels decrease and sex hormone—binding globulin levels increase (causing a further decrease in free or bioavailable testosterone). More than 50% of men older than 55 years of age may have low testosterone, increasingly referred to as *andropause*. Treatment should be considered in all men with testosterone deficiency as long as contraindications do not exist.

Abnormally low testosterone levels are associated not only with sexual dysfunction, but with other comorbid conditions such as lipid disorders, cardiovascular disease, insulin insensitivity, osteoporosis, and cognitive and mood changes. Testosterone deficiency may be a cause of sarcopenia, a condition of aging senescence characterized by muscular weakness and atrophy.

In general, there are two basic types of testosterone deficiency:

- 1. *Primary*, or hypergonadotropic, hypogonadism results from primary testicular failure. In this situation, testosterone levels will be low and levels of pituitary gonadotropins (LH or FSH) will likely be high-normal or elevated.
- Secondary, or hypogonadotropic, hypogonadism is the result of inadequate secretion of pituitary gonadotropins. In addition to a low testosterone level, LH or FSH levels will be low or low-normal.

Satisfactory replacement of testosterone is possible regardless of the type of deficiency.

Hypogonadism is defined as a free testosterone level that is below the lower limit of normal for young adult control subjects. Agerelated decreases in free testosterone were once accepted as "normal." Currently, they are not considered normal. No agreement exists on the exact normal level of testosterone as men age or the serum testosterone level at which a man loses his sexual function.

The definition of *relative hypogonadism* is also uncertain. Many men have perfectly normal sexual function even if their testosterone levels decline into the age-adjusted lower normal range. Patients with low-normal to subnormal testosterone levels may warrant a clinical trial of testosterone. The threshold of response to and dosage of testosterone vary with age. If LH is increased and the testosterone level is low, the patient will have decompensated primary testicular failure. Testosterone replacement therapy can be essential to maintain physiologically normal levels. Testosterone replacement improves sexual function and mood, increases lean muscle mass and strength, and decreases fat mass in hypogonadal men.

An effect of testosterone on endothelial function in men is supported by a recent study that reported on the effects of intravascular administration of physiologic doses of testosterone on coronary blood flow in men with coronary artery disease. The results showed an increase in coronary vasodilation and blood flow in the testosterone test subjects.

## HEALTH IMPLICATIONS OF TESTOSTERONE DEFICIENCY

Testosterone deficiency can result in the following:

- Anemia
- Decreases in or loss of libido and erectile function
- Absence or regression of secondary sexual characteristics
- Oligospermia or azoospermia
- Decrease in energy, increased fatigue
- Depressed mood
- Increase in fat mass
- Progressive decrease in lean body mass and in muscle strength
- Decrease in bone density and increased risk of osteopenia/ osteoporosis

Men with testicular failure may suffer from sexual dysfunction, as well as osteoporosis, muscle weakness, depression, and lassitude, which is the clinical spectrum of hypogonadism. The sexual dysfunction, especially decreased libido and decreased erectile capacity, often reverses with testosterone replacement therapy. Ideally, testosterone therapy should provide physiologic-range testosterone levels (400 to 800 ng/dL). The variability of response in some patients may be related to comorbid medical illnesses, vascular dysfunction causing erectile dysfunction at the penile level, or psychological factors (Box 124-1).

# Box 124-1. Testosterone Deficiency Screening Questions

The "low-testosterone syndrome" often seen in healthy older men is thought to play a role in a number of clinical problems seen in the growing elderly male population. A checklist has been developed to help raise awareness of the presence of testosterone deficiency in the older man. Physicians may find the following questions helpful in screening their older patients:

- 1. Do you have a decrease in libido (sex drive)?
- 2. Do you have a lack of energy?
- 3. Do you have a decrease in strength or endurance?
- 4. Have you lost height?
- 5. Have you noticed a decreased "enjoyment of life"?
- 6. Are you sad or grumpy?
- 7. Are your erections less strong?
- 8. Have you noted a recent deterioration in your ability to play sports?
- 9. Are you falling asleep after dinner?
- 10. Has there been a recent deterioration in your work performance?

### MEN AT INCREASED RISK FOR TESTOSTERONE DEFICIENCY

- Decreased secondary sexual characteristics
- Erectile dysfunction or reduced libido
- An unexplained decrease in energy, or muscle weakness
- Unexplained osteopenia or osteoporosis
- Testicular atrophy
- Human immunodeficiency virus infection/acquired immunodeficiency syndrome with weight loss
- Long-term systemic glucocorticoids
- Chronic alcoholism or substance abuse
- Chronic systemic diseases (e.g., chronic renal failure, chronic inflammatory diseases)
- Recent-onset gynecomastia
- Morbid obesity
- Family history of endocrine failure
- Hypothyroidism

#### **DIAGNOSIS OF TESTOSTERONE DEFICIENCY**

In symptomatic men, these suggested guidelines may be followed:

- Measure total testosterone (total T) by blood measurement taken between 7 and 10 AM.
- A total T above 400 ng/mL is considered normal.
- If total T is between 300 and 400 ng/mL, use the free or bioavailable testosterone level and clinical judgment to guide therapy.
- If total T is less than 300 ng/dL
  - Rule out treatable endocrine causes and transient hypogonadism due to reversible illness, drugs, or nutritional deficiency.
  - Repeat the test and measure free or bioavailable testosterone, LH, and FSH levels.
- If repeat total T or free T is confirmed as low, consider initiating testosterone replacement therapy.
- LH, FSH, or both, are measured to distinguish between primary (testicular) and secondary (pituitary hypothalamic) hypogonadism.
- If FSH and LH are low or normal, this is secondary hypogonadism, and in the presence of very low total T (<150 ng/dL), a</li>

prolactin level and other pituitary hormones should be obtained. If the prolactin level is elevated or other signs of a tumor mass exist, obtain magnetic resonance imaging of the sellar and pituitary region to rule out a pituitary tumor. Referral to an endocrinologist is indicated for further evaluation.

- With a low total T and a high FSH and LH, Klinefelter's syndrome must be considered, which is a common identifiable cause of primary testicular failure and may be diagnosed by obtaining a karyotype.
- A dual-energy x-ray absorptiometry (DEXA) scan may considered to evaluate bone mineral density in men with severe androgen deficiency and fracture risk.

#### **CONTRAINDICATIONS**

- Known or suspected prostate cancer or breast cancer
- Palpable prostate nodule or prostate-specific antigen (PSA) greater than 3 ng/mL without further urologic evaluation
- Severe benign prostatic hypertrophy (BPH) related bladder outlet obstruction or other urinary tract symptoms
- Erythrocytosis (hematocrit >50%)
- Hyperviscosity of blood (hyperviscosity syndrome)
- Treatment for improved athletic performance, body building, or short stature
- Untreated sleep apnea
- Untreated or severe congestive heart failure

# Patients in Whom Treatment Requires Careful Monitoring

- Prostate problems and uncorrected obstructive symptoms caused by BPH
- Edema, fluid retention
- Gynecomastia
- Polycythemia or exacerbated erythropoiesis
- Hypogonadal adolescent boys because treatment may increase physical aggression
- Anyone whose epiphyses have not yet closed, because premature closure and permanent short stature can result from treatment

**NOTE:** It is important to closely monitor those patients with a family history (i.e., presence in a first-degree relative) of prostate cancer, although the relationship between the cancer and testosterone replacement therapy is controversial. A double-blind, randomized, placebo-controlled trial of 237 men 60 to 80 years of age, conducted in the Netherlands from 2004 to 2005 and published in the Journal of the American Medical Association in 2008 (Emmelot-Vonk and colleagues), showed an increase in lean body mass, a decrease in fat mass, increased insulin sensitivity, and no short-term negative effects on the prostate or on cognition. In a review of the literature by Rhoden and Morgentaler in the New England Journal of Medicine in 2004, prospective studies demonstrated a low frequency of prostate cancer in association with testosterone replacement therapy. The conclusion was that there is no compelling evidence at present to suggest that men with higher testosterone levels are at greater risk of prostate cancer or that treating men who have hypogonadism with exogenous androgens increases this risk. It should be recognized that prostate cancer becomes more prevalent exactly at the time of a man's life when testosterone levels decline.

#### **TREATMENT**

Testosterone should be administered only to men who are testosterone deficient, as evidenced by distinctly subnormal serum testosterone levels (<400 ng/dL, or subnormal based on specific assay used). The Endocrine Society's 2006 Clinical Practice Guidelines recommend testosterone therapy for symptomatic men with androgen

deficiency who have low testosterone levels, to induce and maintain secondary sex characteristics and to improve their sexual function, sense of well-being, muscle mass and strength, and bone mineral density.

The principal goals of testosterone therapy are to alleviate symptoms and to reduce health risks by restoring the serum testosterone concentration to the normal range.

The currently acceptable modes of testosterone delivery are transdermal, intramuscular (IM), implantable, and buccal.

**NOTE:** Oral androgens (methyltestosterone, fluoxymesterone) are not as effective and are associated with a significant risk of hepatotoxicity (e.g., cholestatic jaundice, peliosis hepatis, and hepatoma) and are therefore not recommended.

Transdermal testosterone (Testoderm, Androderm): Unlike the original patches applied to scrotal skin, Androderm is worn on the arm or torso and delivers approximately 5 mg in 24 hours. Transdermal therapeutic systems are replaced every 24 hours. Transdermal preparations provide a relatively stable concentration of testosterone compared with other routes. Serum levels of testosterone peak 2 to 8 hours after application of a patch. Anecdotally, as much as one third of men do not tolerate this route because of severe skin rash. This rash may be prevented by pretreating with a topical corticosteroid.

Testosterone gel (AndroGel 1%, Testim 1%) 5-mg packs or tubes: Applied daily to skin, "T gel" is a translucent hydroalcoholic gel that may cause less skin irritation and lower discontinuation rates compared with the transdermal patch. These positive results occur within 30 days. Because of the amount of skin to which the gel is applied, the serum concentrations are more even and higher over 24 hours than with the patch. Testim is dosed at 50 to 100 mg and has a musky aroma. All T gel formulations have a warning about secondary exposure because virilization has been reported in children who were secondarily exposed to testosterone gel. The black box warning states that children should avoid contact with unwashed or unclothed application sites in men using testosterone gel and that health care providers should advise patients to strictly adhere to recommended instructions for use.

Injectable testosterone esters: The principal esters available in North America are testosterone enanthate and testosterone cypionate. Injections of testosterone enanthate or testosterone cypionate may be given at intervals ranging from 7 to 14 days. Dosing typically is 100 mg IM per week to 300 mg IM per 3 weeks. A weekly injection of 100 mg causes less variation outside of the normal range. Although biologically effective, disadvantages of this route include the need for frequent deep IM administration and pronounced fluctuations in energy, mood, and libido (particularly as the dosing interval is increased). Testosterone undecanoate (Nebido) is available in several countries and is dosed at 100 mg every 3 months.

Implantable hormone pellets (Testopel): The implantable pellets are perhaps the most convenient, dependable, and best-tolerated method of testosterone delivery. Subcutaneous pellets are viewed as a more cost-effective and convenient therapy with potentially much greater compliance and tolerance than other methods. Placed subcutaneously in the buttocks through a special trocar device, 8 to 10 pellets (600–750 mg) usually provide sustained adequate physiologic blood levels (e.g., 400 to 800 ng/dL) for 4 to 6 months (Box 124-2).

Buccal tablet: The U.S. Food and Drug Administration approved Striant (30 mg, twice a day) in June 2003. It is adhered to a depression in the gum above the upper incisors.

Finally, although not an androgen, human chorionic gonadotropin (hCG) stimulates production of testosterone and sperm by the testes.

# Box 124-2. Insurance Criteria for Reimbursement for Testosterone Pellets

Aetna, U.S. Healthcare, BlueCross/Blue Shield, and Medicare cover U.S. Food and Drug Administration—approved implantable testosterone pellets (Testopel pellets) subject to the following patient selection criteria only:

- As second-line testosterone replacement therapy in men
  with congenital or acquired endogenous androgen
  absence or deficiency associated with primary or
  secondary hypogonadism when neither transdermal
  nor intramuscular testosterone replacement therapy is
  effective or appropriate.
- Primary hypogonadism includes conditions such as testicular failure as a result of cryptorchidism, bilateral torsion, orchitis, vanishing testis syndrome, inborn errors in testosterone biosynthesis, or bilateral orchiectomy.
- Secondary hypogonadism (hypogonadotropic hypogonadism) includes conditions such as gonadotropinreleasing hormone deficiency and pituitary—hypothalamic injury as a result of surgery, tumors, trauma, or radiation, and is the most common form of hypogonadism seen in older adults.

# MONITORING PATIENTS ON TESTOSTERONE REPLACEMENT

- Clinical symptoms and signs of testosterone deficiency
- Frequency and duration of erections
- Acne and oiliness of skin, breast size and tenderness
- Possible skin irritation with transdermal therapy
- Serum testosterone levels
- Lipid profiles
- Sleep apnea

Transdermal testosterone delivery systems: Serum testosterone should be drawn 8 to 12 hours after application or per patch label instructions. Because concentrations fluctuate in an unpredictable way when using the gel preparation, at least two measurements should be obtained. Skin irritation at the site of the patch is common.

Injectable or implantable testosterone: Monitor nadir testosterone levels at 3 months (implants) or before the next injection/ implantation. Levels that exceed 800 ng/dL or are less than 200 ng/dL require adjustment of the dose or frequency.

Digital rectal examination (DRE) and PSA: DRE should be performed and a PSA level checked in all men before initiating treatment, again at 3 months, and then annually in men older than 40 years of age. An abnormal DRE, a confirmed increase in PSA of more than 1.4 ng/mL in any 1-year period, a total PSA of more than 4.0 ng/mL, or a PSA velocity of greater than 0.4 ng/mL per year (beginning 6 months after therapy initiation) requires evaluation by a urologist. Exacerbations of obstructive uropathy related to BPH are a concern, and, if warranted, urine flow rate and postvoid residuals should be measured.

Hematocrit: Testosterone replacement therapy has been associated with increased hematocrit and hemoglobin. The hematocrit should be checked at baseline, then at 3 months and yearly. A hematocrit of more than 52% warrants evaluation for hypoxia and sleep apnea or a reduction in the dose of testosterone therapy. Testosterone is known to stimulate erythropoiesis.

Sleep apnea: Screening for sleep apnea includes interrogation of symptoms (e.g., excessive daytime sleepiness, snoring, or witnessed apnea) and polysomnography when indicated.

Liver function, cholesterol, and high-density lipoprotein (HDL) cholesterol: Levels should be checked periodically. Testosterone lowers total cholesterol, low-density lipoprotein, and HDL.

Breast examination: Regular breast examinations are recommended. Bone mineral density: Measurement of bone mineral density of the lumbar spine or the femoral necks at 1-year intervals may be considered in hypogonadal men with osteopenia, especially those younger than 80 years of age.

#### **EQUIPMENT**

- Trocar implanter kit (includes the trocar and stylet plunger)
- Disposable 5-cm trocar pellet implanter (3.2-mm bore diameter)
- Forceps
- Stainless steel tray
- Sterile gloves
- 1% lidocaine with epinephrine 2 to 3 mL
- 3-mL syringe; 27-gauge, 1½-inch needle
- No. 11 scalpel blade
- 75-mg testosterone pellets (Testopel; Slate Pharmaceuticals),
   3 × 8 mm (most common total dose for 4 to 6 months is 10 pellets), in individual sterile glass tubes
- Lidoderm 5% patch or topical anesthetic placed 15 minutes before the procedure at site of insertion (optional)
- 2.0 chromic suture or Steri-Strips and tincture of benzoin

**NOTE:** The disposable trocar should be sterile and individually packaged. If an older stainless steel trocar is used, it should be sterilized by steam in an autoclave at 121° C for a minimum of 15 minutes. The standard procedures for sterilizing surgical instruments should be followed.

#### PREPROCEDURE PATIENT PREPARATION

All potential risks, benefits, and alternatives to testosterone replacement therapy should be discussed, specifically the potential complications regarding trocar insertion subcutaneously (including infection and bleeding). The patient should understand that once the pellets are inserted, they are not typically removed unless the risks outweigh the benefits. The pellets slowly dissolve and the effects will last for 4 to 6 months.

The office procedure usually takes approximately 15 minutes. The testosterone pellets should be implanted into the subdermal fat of the buttocks using a special trocar implanter under sterile conditions and using a local anesthetic. The 75-mg pellets are fat soluble and so are implanted subcutaneously. In most men, an area on either lateral buttock between the gluteus maximus and the tensor fasciae latae muscle is preferred so that implantation is made below the skin and above the muscle and fascia, just inferior to the iliac spine, directed inferiorly along the line of the femur. The skin is marked 3 cm below the halfway mark between the iliac crest and the sacroiliac joint and the line is extended about 10 cm inferiorly parallel to the femur. Anecdotally, pellets implanted more superiorly near the belt line or in the buttock on the side under the wallet pocket have been subject to inadvertent extrusion (Fig. 124-1A).

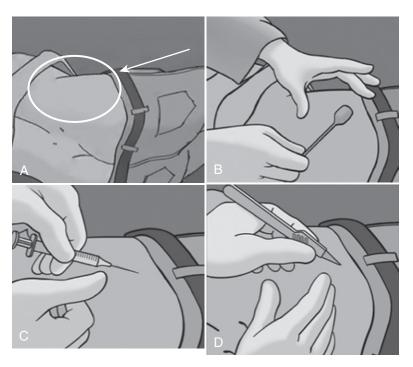

#### **Preparation**

**TECHNIQUE** 

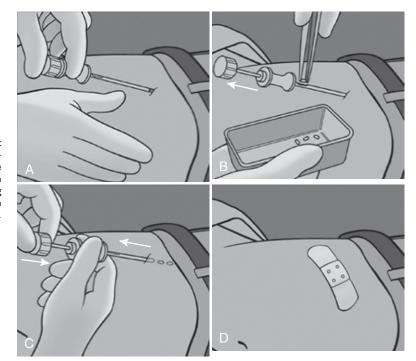

- Place patient comfortably in the lateral jackknife or fetal position.
- 2. Cleanse the skin over the insertion site with Hibiclens, alcohol, and povidone–iodine (Fig. 124-1B).
- 3. Sterile technique is used.
- 4. Create a skin wheal using lidocaine 1% with epinephrine (1:100,000; Fig. 124-1C).
- 5. Inject 2 to 3 mL of 1% lidocaine with epinephrine along the intended tract of the trocar insertion to a depth of 2 cm.

#### **Implantation**

- 1. Place pellets as indicated in the sterile container (the most common dose is ten 75-mg pellets).
- 2. After adequate local anesthesia, make a small (4-mm) puncture incision with a no. 11 scalpel blade (Fig. 124-1D).
- Insert the trocar with stylet (solid rod in metal sheath with pointed end), direct it subcutaneously pointed at a 30-degree angle to the skin surface, and advance it inferiorly to a depth of 2 cm.
- 4. The trocar and stylet are then angled horizontal to the skin surface and advanced beneath the skin through the

**Figure 124-1** Preparation for implantation of testosterone pellets. **A** and **B**, Cleanse skin with Hibiclens, alcohol, and povidone–iodine. **C**, Create skin wheal using lidocaine 1% with epinephrine. **D**, Make small incision with no. 11 blade. (Courtesy of Slate Pharmaceuticals, Inc., Durham, NC.)

**Figure 124-2** Implantation of testosterone pellets. **A,** Insert the trocar implanter with the stylet in place and direct it subcutaneously to the depth of the bolt (about 5 cm). **B,** Remove the stylet and place all the pellets in the lumen of the implanter with sterilized tissue forceps. **C,** Insert the stylet and, while stabilizing and slowly pulling back the implanter, push the pellets through the bore and into the fatty tissues. **D,** Close the puncture site. (Courtesy of Slate Pharmaceuticals, Inc, Durham, NC.)

subcutaneous tissue above the muscle and parallel to the trajectory of the femur to full depth (about 5 cm) until reaching the pellet slot (Fig. 124-2A).

- 5. The pointed stylet is then removed, and, using sterile tissue forceps, pellet implants are carefully placed in the slot of the hollow tube of the implanter. Usually, three to five pellets per tract are placed (Fig. 124-2B). (A sterile tray or cup may be held beneath the implanter as a "safety net" to catch pellets that may be inadvertently misplaced.)
- 6. The stylet is then inserted into the trocar to be used as a plunger. The implanter is stabilized with one hand as the pellets are pushed through the bore and advanced within the hollow trocar sheath. The stylet is advanced inside the trocar as the trocar is slowly withdrawn, and the pellets are pushed out and deposited into the fatty tissue (Fig. 124-2C).
- 7. This insertion process may be repeated through the same incision in a fanlike fashion until the total dose (usually 10 pellets) is deeply inserted. Extrusions may be minimized by placing pellets in tracts arranged in a fanlike pattern (e.g., three, four, and three at 45, 90, and 135 degrees, respectively).
- 8. After all the pellets have been inserted, the stylet is advanced within the trocar and the trocar is withdrawn using a clockwise–counterclockwise twisting motion.
- 9. Give the patient a dry pressure dressing to apply pressure for a few minutes.
- 10. Clean and then close the puncture site using Steri-Strips or a chromic suture, and cover with an adhesive bandage (Fig. 124-2D). Cold compression using body weight on an ice pack is advised for 10 minutes.

The pellets are slowly absorbed and are not removed. The procedure may be repeated on the opposite buttock in 4 to 6 months, depending on the adequacy of serum testosterone. Have the patient return in 3 months to check for efficacy and tolerability.

#### **COMPLICATIONS AND RISKS**

The chief adverse reactions with testosterone pellets include the following:

- Pellet extrusion
- Minor bleeding (typically insignificant and controlled by applying pressure to the surgical wound)
- Infection (infrequent and may also result in pellet extrusion)

The use of povidone–iodine skin disinfectant before the procedure appears to lower pellet extrusion rates. The likelihood of pellet extrusion may decline with increasing operator experience. Preoperative and postoperative oral antibiotics (e.g., cephalexin 1000 mg) may reduce the incidence of infection. Some patients develop fibrosis (scarring, nodules) around implantation sites, but this typically does not prevent further implantations.

Other, rare, complications include the following:

- Pain at insertion site
- Increased fluid retention
- Gvnecomastia
- Worsening sleep apnea
- Increased hematocrit
- Worsening prostate symptoms
- Testicular atrophy
- Mood swings
- Oligospermia or azoospermia

#### POSTPROCEDURE PATIENT EDUCATION

Most patients return to work the day of, or the day after, implantation but are advised to avoid bending or vigorous physical activity. For the first 24 hours, the patient should keep a dry pressure bandage on the insertion site and limit strenuous activity. He should watch for any complications as noted previously.

#### REGULATIONS

Testopel pellets are classified as a Schedule III controlled substance under the Anabolic Steroids Act of 1990. Physicians should restrict usage to avoid long-term on-site storage. As with other Schedule III substances, it is necessary to strictly follow state pharmacy and federal Drug Enforcement Agency regulations, and always

document and copy. A prescription may be written and the patient may obtain the pellets and bring them to the clinic for insertion, or the pellets and trocar may be ordered directly from Slate Pharmaceuticals (Durham, NC). Slate has an updated website for additional reference (www.Testopel.com).

# VACUUM DEVICES FOR ERECTILE DYSFUNCTION

John R. Holman

Erectile dysfunction is a common medical problem occurring in nearly 30 million American men. Vacuum devices to promote erection are safe and have overall clinical success rates of approximately 90% but are considered second-line therapy given the efficacy, favorable side effect profile, and ease of use of phosphodiesterase inhibitors. They are useful in nearly all men with erectile dysfunction except those with severe cavernous fibrosis. Therapy depends on the ability to transfer blood into the corpus cavernosa, which is limited if fibrosis is present.

A number of devices are available for use. The majority have three common components: a vacuum chamber or cylinder, a vacuum pump that creates a negative pressure within the chamber, and an elastic constriction band.

The devices create a nonphysiologic erection by trapping blood in both the intracorporeal and extracorporeal compartments of the penile shaft by means of the negative-pressure vacuum. The constrictor band is then placed before the chamber, over the proximal shaft, constricting blood flow into and out of the penis and maintaining an erection for sexual intercourse. Erection is maintained distal to the constricting band. Most manufacturers recommend that the vacuum-induced erection be maintained for less than 30 minutes because penile distention, edema, and cyanosis may ensue with prolonged use. The American Urologic Association, in its erectile dysfunction clinical practice guideline, reviewed and validated in 2009 and based on panel consensus, recommends only vacuum constriction devices containing a vacuum limiter—relief valve should be used, whether purchased over-the-counter or procured with a prescription.

#### **INDICATIONS**

Erectile dysfunction resulting from

- Vascular disorders
- Neurologic disorders
- Psychogenic disorders
- Hormonal disorders
- Medications, when the medication cannot be altered or terminated

#### **CONTRAINDICATIONS**

- Blood dyscrasias, coagulation disorders, or anticoagulation drug therapy
- Impaired manual dexterity to operate the device

#### **EQUIPMENT**

 Vacuum erection device, including chamber, vacuum pump, and constriction bands (Fig. 125-1A). Battery-operated suction

- devices may be preferable in patients with impaired manual dexterity or after debilitating neurologic events such as stroke or quadriplegia. Constriction bands come in a variety of sizes to fit the penile shaft.
- Lubricant as needed.

#### PREPROCEDURE PATIENT PREPARATION

Discuss use of the suction device, alternatives, relative benefits, and potential complications with the patient and, when possible, his partner. The patient should be aware that a vacuum-induced erection, unlike a physiologic erection, causes rigidity distal to the constrictor band and may allow the penis to pivot at its base, requiring positioning for vaginal penetration. Although it is generally well tolerated, patients using this device may experience painful ejaculation, penile pain, ecchymoses, hematomas, petechiae, and decreased penile temperature or numbness distal to the constriction band. Most men have normal ejaculations with vacuum devices. Delayed or painful ejaculations have been reported in 10% to 15% of men, along with a feeling of trapped semen during ejaculation. The use of constriction rings with a "cut out" on the ventral aspect of the ring can help prevent this (Fig. 125-1B). Otherwise, the semen drains out the penile meatus once the constriction band is removed. Hematomas have been reported in 9.8% and local skin injury in 2.2% of long-term users. These complications can be reduced or eliminated by increased experience with the device and by emphasizing the need to remove the constriction band after 30 minutes. Most manufacturers provide instructional materials, videos, and customer service availability by phone to assist with appropriate use of their equipment.

#### **TECHNIQUE**

- 1. Complete the patient's history and physical examination to establish a diagnosis of erectile dysfunction.
- 2. Select a desired device for use.
- Apply the open end of the vacuum chamber over the penis. A seal should be made with the skin at the base of the penis, usually with the help of lubricant jelly.
- 4. Activate the vacuum pump to create negative pressure within the chamber, thereby drawing blood into the penis and producing an erection-like state. Most devices have release valves in the chamber that prevent formation of excessive pressure (Fig. 125-1C).
- 5. Once adequate tumescence is achieved, slide the constrictor band at the base of the chamber onto the penile shaft. This effectively traps blood in the penis to maintain the erection. The chamber and pump may now be removed. Constrictor bands are available in a variety of sizes.

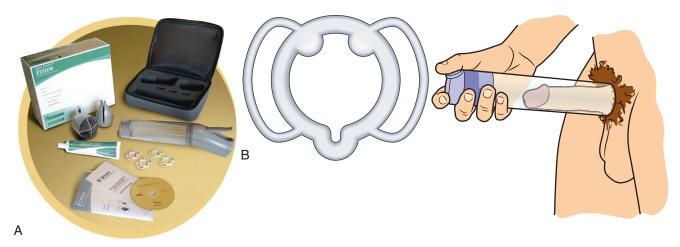

Figure 125-1 A, Typical vacuum device for erectile dysfunction. B, Constricting rings on device, cross-sectional view. C, How to activate the pump. (A, Courtesy of TIMM Medical Technologies, Eden Prairie, Minn. B, Redrawn from TIMM Medical Technologies.)

- 6. After intercourse, remove the band from the penile shaft. The vacuum-induced erection will subside.
- 7. Inspect the penis for evidence of injury.
- 8. After use, submerge all parts of the suction devices, except the vacuum pump, in soapy water for cleaning.

#### **COMPLICATIONS**

- Decrease in penile temperature or numbness distal to the constriction band.
- Local skin injury.
- Painful ejaculation.
- No ejaculation.
- Penile pain.
- Subcutaneous ecchymoses, petechiae, or hematoma.
- With prolonged use (>30 minutes), progressive penile distention, edema, and cyanosis may occur.

### **VASECTOMY**

Charles L. Wilson

Vasectomy is a safe, inexpensive, permanent form of contraception. Ten per 1000 men 25 to 49 years of age have a vasectomy annually in the United States, totaling between 500,000 and 600,000 per year. In comparison, there are somewhere between 600,000 and 700,000 tubal ligations per year, with about half being performed postpartum. Unlike tubal ligation, vasectomy is usually performed in an office setting, is less expensive, and is associated with fewer and less severe complications. No mortality from vasectomy has been reported, whereas approximately 10 women die annually from complications of tubal ligation in the United States. Although both procedures have low failure rates, a failure of tubal ligation is discovered only when pregnancy occurs, whereas failure of vasectomy can be detected by routine postvasectomy semen testing. Thus, vasectomy offers high efficacy with lower morbidity and lower cost, yet it continues to be underused.

The decision process that leads up to the choice of vasectomy often starts with a general discussion of birth control options and family planning, which may involve the primary care physician or the partner's gynecologic care provider. It is essential that these providers be knowledgeable and prepared to provide accurate information about vasectomy to the man and his partner.

Patient education handouts for this chapter are available online at www.expertconsult.com. Explicit patient instructions are imperative, especially in this procedure. The patient education handouts are highly recommended for this purpose.

As discussed later in the section on Technique Variations, vasectomy can be performed in many ways. In the mid-1980s, EngenderHealth (formerly AVSC International) helped popularize the *no-scalpel vasectomy* (NSV), a method devised in China by Dr. Li Shunqiang. China was at that time struggling against a 2:1 bias favoring tubal ligation over vasectomy. Dr. Li designed a vas fixation clamp and sharp dissecting forceps (SDF), which allowed him to perform vasectomy in a "refined" and less invasive manner. NSV became widely accepted by Chinese men. Whether NSV is, in practice, less invasive than the traditional methods depends entirely on the training, skill, and experience of the surgeon. Certainly it has been demonstrated in some hands to be a quick, virtually bloodless, and often painless procedure. It lends itself to a significant psychological advantage with the apprehensive patient.

Similarly, the "no-needle no-scalpel vasectomy," or more simply, no-needle vasectomy (NNV) technique, devised by the author in 1999, replaces the previous skin wheal and vasal block anesthetic with a jet injection, and helps relieve patients' fear of needle administration of anesthetic in this sensitive area (Wilson, 2001).

In any case, the no-needle and no-scalpel approaches simply define *methods of anesthesia and of entry and access to the vas deferens*. How the vas deferens is then occluded is variable and a matter of preference

The term *laser vasectomy* has been used to refer to the minimally invasive techniques, but in reality there is no practical use or value for a laser in the vasectomy procedure.

The long-sought goal of a completely reversible vas occlusion method has spawned experimental models of occlusion without

dividing the vas deferens. Such methods include simply clamping the vas with metal vascular clips or with the plastic VasClip (VMBC, LLC, Roseville, Minn), injecting glues or scarifying agents into the lumen, implanting silicone plugs, or simply cauterizing a length of the lumen transcutaneously. None of these methods has proven sufficiently successful or reversible.

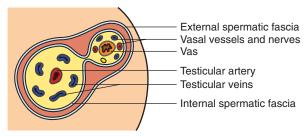

#### **ANATOMY**

The scrotal epidermis is very thin and the dermis is supported by the thick and elastic dartos muscle. These layers are well endowed with blood vessels, which makes them susceptible to bleeding and ecchymosis; however, they are also particularly resistant to infection and capable of rapid healing after surgical incision. The scrotum can vary widely among patients in its size, shape, and texture (from that of a full, round, tense cyst that resists palpation; to a thin, smooth, droopy sac with nearly visible contents; or a flat, rugous thickening along the dependent fold of an abdominal panniculus). Individual anatomy plays the largest role in determining whether a vasectomy will be easy or difficult to perform. A septum separates the left and right sides of the scrotum, and loose connective tissue cushions the scrotal contents. In single-incision vasectomy, the septum does not present a practical barrier, and bleeding risk is less than with two separate incisions.

The *epididymis* is a soft, comma-shaped attachment on the testis that originates at the superior pole and wraps around the back down to the inferior pole, clinging to the smooth, firm surface of the testis, but separated by a sulcus. (See patient education worksheet online at www.expertconsult.com.)

The vas deferens originates as a convoluted, tenuous duct from the tail of the epididymis at the inferior pole of the testis. As it courses cephalad along the posteromedial aspect of the spermatic cord, it becomes straight and sturdy, with thick walls of smooth muscle tissue, which give it a dense, almost gritty texture to palpation. In a cross-section of the scrotum above the level of the testicles, the vas is a prominent tubular structure surrounded by tiny vasal nerves and supplied by its own small deferential artery (Fig. 126-1). It is deep within the scrotum, separated from the skin surface by nine tissue layers, the deepest of which is the internal spermatic fascia, which also contains the testicular artery, lymphatics, and nerves, and the pampiniform plexus. At that level it is usually distinctly palpable and firm, about 3 mm in thickness, like a hard-cooked spaghetti noodle or a ball-point pen refill. But anatomic variation accounts for vasa that may be as thin as 1.5 mm or as thick as 4.5 mm. Occasionally, the convoluted portion extends all the way to the inguinal canal. Some patients have congenital absence of the vas on one side, although they are rarely aware of it.

Sensation in the anterior scrotum is mediated by the ilioinguinal nerves and the perineal nerves arising from the pudendal nerves. Complete anesthesia for vasectomy depends on blocking not only these somatic sensory paths, but the autonomic afferents that supply the vas deferens with its visceral sensation.

**Figure 126-1** Schematic coronal view of spermatic cord and internal structures. Note location of vas deferens with its associated vessels and nerves, as well as the testicular artery and veins, all located within the internal spermatic fascia.

#### **INDICATIONS**

- Vasectomy is appropriate for a man when he (and usually his partner) have decided they do not wish to have children, or to have any more children.
- For some couples there is a medical contraindication to pregnancy in the female partner or a commitment to adopt children in lieu of having their own.
- Occasionally a man seeks vasectomy as extra assurance even though his partner has had a tubal ligation or a history of infertility.
- A man diagnosed with a genetic contraindication to fathering a child may desire vasectomy.

#### **CONTRAINDICATIONS**

#### Absolute

- Bacterial skin infection
- Uncontrolled coagulation disorders
- Inability to palpate and elevate both vasa
- Hypersensitivity to palpation, precluding isolation of the vas
- Lack of adequate informed consent
- Depression, psychosexual impairment, or impaired decision making

#### **Relative**

- Anticoagulant or antiplatelet therapy. Aspirin and clopidogrel (Plavix) should ideally be stopped for 5 days before the surgery and for 2 to 3 days afterward. Each case should be evaluated individually and if the medications cannot be stopped, meticulous hemostasis must be ensured at the time of surgery.
- Impending infertility, such as menopause or hysterectomy in partner.
- Unresolved conflict or stress, for example recent childbirth, marital discord, divorce or financial setback.
- Inappropriate expectations of vasectomy (e.g., improving a troubled marriage, curing sexual problems).
- Excessive, unreassured concerns regarding sexual functioning after the vasectomy.

#### PREPROCEDURE PATIENT PREPARATION

Patient education materials and handouts are widely used and are of great value in preparing the patient for vasectomy. The vasectomy questionnaire, patient education handouts, and patient consent forms help achieve fully informed consent. (See all of these forms online at www.expertconsult.com.)

Schedule a preoperative consultation and evaluation at least several days before the scheduled procedure. This allows time for the patient and his partner to think about the decision and the information provided before the procedure. This appointment will generally take 15 minutes if prior patient education material has been reviewed by the patient or if he has reviewed a counseling video. Without these materials, it may take 30 minutes to properly inform the patient and answer all questions.

Many now recognize the educational value of patient education videotapes/DVDs. The patient can review the material several times privately at home. A vasectomy counseling videotape is available from Creative Health Communications through The National Procedures Institute (see the Suppliers section). With portable DVD players, the patient can easily view the material in the office before seeing the physician.

The patient should sign the formal consent form. The consent form may be titled "Request for Vasectomy" to emphasize the patient's role in decision making. The physician still retains responsibility to help the patient make a decision that will be in his best long-term interest. It is wise to include the wife or partner, if any, in the consent process; however, a man has the right to choose vasectomy even in the absence of spousal consent. Similarly, a patient who is young, unmarried, or without children should not be denied vasectomy on these grounds alone.

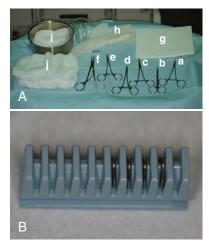

The preprocedure counseling visit can be documented using the encounter form, which reviews the patient's pertinent history, physical examination, and counseling points, and documents the follow-up semen specimen checks. The form can be found online at www.expertconsult.com.

At the conclusion of the session, perform a careful *genital examination*, noting any anomalies of the area and especially the size, texture, and position of the vasa deferentia as they course through the upper scrotum. Be alert to the possible absence of a vas or presence of a third or fourth vas, although such cases are extremely rare. Make a mental note of the ease or difficulty of mobilizing each vas to the anterior midline, and make a final decision whether to proceed with this vasectomy or stop and refer. Check for testicular masses, varicoceles, inguinal hernias, and possible granulomas. Note any tenderness to palpation. Groin rashes should be resolved before surgery.

Also helpful is the Patient Education Worksheet, which also is available online at www.expertconsult.com. This is a checklist of the counseling material to be reviewed with the patient. The original sheet is for the patient and a copy is made for the chart. Not only is it a good summary of all points covered, but it serves as a reminder for the patient of what to do just before and after the surgery. (For a more detailed description of the preprocedural counseling visit, see Pfenninger [1984b].)

The clinician should note the questions, "How well do you tolerate pain?" and "Do you have a tendency to faint?" on the encounter form. If the patient tolerates pain poorly or has a tendency to faint, atropine 0.5 mg may be given intramuscularly on arrival to the office before surgery to reduce vasovagal effects of nausea, bradycardia, and syncope. This optimizes the "vasectomy experience" for both the patient and physician. Oral sedation with either diazepam 10 mg or alprazolam 1 mg 1 hour before surgery may be used in addition to the atropine or alone to help relax the nervous patient. Sedation, however, requires that he avoid driving and other activities requiring alertness for the rest of the day. One may plan to prescribe a narcotic analgesic for patients who indicate above-average sensitivity to pain based on their prior experiences. However, a nonsteroidal anti-inflammatory drug (NSAID) such as ibuprofen 800 mg is usually adequate and safe. Some now use tramadol (Ultram) 100 mg.

To minimize risk of bleeding complications, patients on antiplatelet therapy should have their platelet function restored by the time of surgery. This requires abstaining from aspirincontaining products and clopidogrel for 5 days. NSAIDs (except cyclooxygenase-2 inhibitors) in very rare instances are associated with bleeding. If a patient does have a questionable history, NSAIDs should be withheld for 48 hours before and after surgery. If there is no history of bleeding disorder or prior complications of surgery, normal platelet function can usually be assumed.

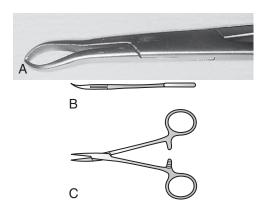

**Figure 126-2 A,** The surgical tray: sharp dissecting forceps (a); scissors (b); straight mosquito hemostats (c); curved mosquito hemostats (d); Wilson vasectomy forceps (e); hemoclip applicator with clips (f); pack of  $4 \times 4$  gauze (g); battery cautery in sterile glove (h); basin of wet gauze pads (i); large number of "fluffed-up" gauze pads to place inside scrotal supporter (j). **B,** Close-up of hemoclip pack with four clips remaining.

Federal agencies require that a specific consent form be executed for the physician to be compensated. These are usually available from local health departments or the state Medicaid agency. Forms must be completed fully and accurately to avoid denial of payment. Note that consents are valid only for surgery performed more than 30 days and less than 180 days after the counseling session at which the form is signed.

#### **EQUIPMENT AND SUPPLIES**

The preparation for vasectomy includes gathering the necessary equipment and supplies and arranging the sterile items on a surgical tray (Fig. 126-2). Each setup depends on the surgical setting and the surgeon's preferred technique and choice of available supplies. A checklist for the staff to use in preparing for the procedure is a good way to avoid omissions and oversights.

 Vas-fixing forceps (VFF; one or two pairs) are locking clamps used to secure the vas during puncture and dissection (Fig. 126-3A). Historically, sharp or blunted towel clips have been popular. The Wilson vasectomy forceps (Advanced Meditech International [AMI], Flushing, NY; Marina Medical, Sunrise, Fla) provide a

**Figure 126-3** No-scalpel instruments. **A,** Wilson vasectomy forceps. **B** and **C,** Sharp dissecting forceps. (**B** and **C,** From Li SQ, Goldstein M, Zhu J, Huber D: The no-scalpel vasectomy. J Urol 145:341–344, 1991.)

**Figure 126-4** Battery-operated cautery unit with disposable tip. (Courtesy of Advanced Meditech International, Flushing, NY).

secure yet atraumatic grasp of the vas for incisional vasectomy, and work equally as well as VFF in the no-scalpel technique. The *Li* vasectomy forceps (AMI) were introduced in China as VFF for NSV. They feature a cantilever design to limit closing force.

- Sharp dissecting forceps (SDF; AMI, Marina Medical) are the key to atraumatic dissection of the vas and are used to puncture the skin instead of a scalpel incision and to hook and deliver the vas. They are essentially sharp-pointed hemostats (Fig. 126-3B and C).
- If a scalpel will be used for incision or sharp dissection, include a disposable scalpel or scalpel handle with a no. 15 blade.
- Cautery unit, either an electrocautery unit and handpiece, with a
  fine-needle electrode (unit should be set at the lowest level that
  quickly cauterizes small "bleeders"), or a battery unit. Batterypowered thermal cautery units with disposable sterile sheaths and
  disposable specialized vasectomy tips are available from AMI
  (Fig. 126-4). Based on Schmidt's (1992) findings, a batterypowered cautery unit may be the instrument of choice for optimal
  sealing of the vas ends compared with an electrosurgical unit.
- Three mosquito hemostats.
- Adson tissue forceps (1 × 2 teeth) with suture platform for holding the vas or fascia.
- Tissue scissors for dividing or hemitransecting the vas.
- Method to seal vas sheath: Either a needle holder with a 4-0 absorbable plain, chromic, or polyglycolic acid suture on an atraumatic needle or a medium hemoclip applicator with clips.
- A method to anesthetize the area: Traditionally, a 10-mL syringe (1½-inch, 27-gauge needle) with lidocaine (2%) without epinephrine (10 mL) was used. In the NNV anesthesia technique (see later discussion), an instrument called the MadaJet is used to administer the lidocaine. Only 0.1 mL of lidocaine is used per side with this instrument, but it requires at least 1 mL in the chamber to prime and function correctly.
- Sterile sodium bicarbonate solution to mitigate pain during anesthetic infiltration if needle injection is used (optional). Just before injection of the anesthetic, the clinician should draw up 1 mL of sodium bicarbonate with 9 mL of the lidocaine. This reduces the "sting and burning" associated when lidocaine is injected. Sodium bicarbonate is not needed if the MadaJet is used.
- Large pack of  $4 \times 4$  gauze.
- A povidone-iodine (Betadine) or chlorhexidine (Hibiclens) preparation.
- Fenestrated sterile drape and nonfenestrated drape.
- Sterile gloves and mask.
- Single sterile glove (into which the cautery device is placed if the sterile cautery sheaths are not used). This is not needed if a sterile cautery handset is used.
- Pair of nonsterile gloves for preparation.
- Specimen jar with formalin.

# NO-NEEDLE VASECTOMY ANESTHESIA TECHNIQUE

In the NNV technique, the traditional vasal block method is replaced by the no-needle technique. This is accomplished using a piston-like instrument (MadaJet 401UR; Mada Medical, Inc., Carlstadt, NJ; Fig. 126-5A), which uses the force of fluid under pressure to "push" the anesthetic into the tissues. The jet injection is a fine stream (about 0.006 inch in diameter) that instantly

**Figure 126-5 A,** MadaJet model 401UR with metal sheath that fits over the nozzle tip to align the stream with the vas. **B,** Stream of lidocaine emitted from the MadaJet orifice.

penetrates about 4 mm through the skin and vas deferens, producing an almost immediate and complete anesthetic effect (Fig. 126-5B).

The vas should be isolated as described later in step 3 of the No-Scalpel Vasectomy Procedure section. However, now both the index and middle fingers are placed behind the scrotum with the thumb in front. The straight segment of vas spans a small "safe" space between the index and middle fingers. The MadaJet is cocked and the tip is then placed firmly over the vas next to the thumb, directed into the "safe" space, and actuated by pushing the button. Each injection will be 0.1 mL of lidocaine. When beginning, it may help to mark the intended site of the scrotum with a marking pen and then isolate the vas to this spot for anesthesia. The marked spot will make it easier to bring the other vas to the same location. It also identifies where the opening should be made. A second application can be made over each vas to ensure a good block if desired. The total amount of anesthetic will then be 0.2 to 0.4 mL.

**CAUTION:** Be careful *not* to have fingers positioned behind the vas in line with the jet injection stream. Lidocaine can penetrate through the patient's tissues and into the surgeon's fingers. This is the reason for the special finger positions for NNV.

The MadaJet 401UR is supplied with the proper settings for NNV and comes with a stainless-steel spacer, which is notched to conform to the vas. The MadaJet design incorporates air space

between the tip of the injector and the skin, so it does not require disposable parts like other injectors do. It does, however, demand careful attention to cleaning, sterilization, and maintenance procedures between uses according to the manufacturer's instructions.

After each patient use, careful sterilization of the MadaJet is essential. The entire MadaJet may be routinely autoclaved, but that is not necessary between patient uses. After use, the device is fired once to clean the exit port, then the tip, spacer, and body are cleaned, and the entire tip end of the device is cold sterilized by immersion in Madacide-FD solution for at least 10 minutes. The reservoir tube holds 4 mL of lidocaine, enough for about 40 actuations. At the end of each day, the MadaJet is disassembled, cleaned, and autoclaved. Periodic maintenance, at least annually, is required and is performed by the manufacturer.

There are several *advantages to NNV*. First, no needle penetrates the skin, reducing the risk of bleeding complications related to needle damage. Second, needlestick risk for surgical personnel is avoided, and medical waste is reduced. Third, it relieves patients of fears they may have about needles—this benefit cannot be overestimated. (The hypospray is very efficient. In over 11,000 NNVs by the author, 97% required only one injection for each vas. That is only 0.2 mL of lidocaine per patient, or about 1/30 the usual amount required for the complete vasectomy. It is so effective that even "slow responders" to local anesthetics experience rapid numbness.)

The major limitation of NNV is the small area of numbness, about the size of a dime. With advanced skills and precision in NSV technique, a physician can incorporate the no-needle anesthetic technique successfully. Otherwise, more injections to include adjacent tissues will be required to keep the patient comfortable.

Physicians will find a myriad of other applications for the MadaJet among the procedures they perform in the office. "No-needle anesthesia" will be embraced by many patients in addition to men undergoing vasectomy. A single "snap" suffices for a punch biopsy, injecting scars with steroids, skin tag excision, or skin anesthesia before needling for joint aspiration or injection or fine-needle aspiration of the breast, to name a few examples. A special dermatologic tip is needed for these applications.

#### **TECHNIQUE VARIATIONS**

# Traditional Vasectomy versus No-Scalpel Vasectomy Technique

In both techniques, the anesthetized vas is manipulated to lie under the skin of the scrotum where the opening will be made. Traditional technique may involve two separate anterolateral incisions (one for each vas) in the scrotum, although increasingly a single midline entry is used. The NSV technique specifies a single opening located in the anterior midline of the scrotum, between the upper one third and the lower two thirds of the scrotum.

The essential difference is in the method of entry through the skin and in the delivery of the vas. In the traditional technique, a typical surgical incision 1 to 2 cm long is made in the skin with a scalpel, then carried through the dartos and fascial layers sequentially until the vas is exposed and bluntly dissected free of the fascia. Bleeding is controlled at each layer, as needed, usually with cautery.

In the NSV technique, the method of entry is reduced to three smooth, precise movements, eliminating most of the operating time, tissue trauma, bleeding, and hemostatic maneuvers of traditional vasectomy. The key is the SDF. It is held and used in a precise manner to puncture the skin, all layers of fascia, and the anterior wall of the vas deferens in one smooth motion. It is then used to dilate the resulting 2-mm tract by stretching, not cutting, all layers at once. Finally, the tip of the SDF is precisely placed in the vas and rotated to hook the vas and deliver it cleanly from the fascial sheath, minimizing dissection.

Once the vas is delivered, there is no distinction between traditional and NSV in how one proceeds with occlusion of the vas, and

alternatives are discussed in the following section. After occlusion of the vasa, traditional scalpel incisions are usually closed with one or two sutures, whereas the small stretched opening of NSV contracts and rarely requires closure.

#### **Occlusion Methods**

A number of occlusion techniques have been used, with varying degrees of success, but existing evidence is insufficient to recommend one specific technique (Sokal and Labrecque, 2009).

Traditional division of the vas and suture ligation of both ends has a 1% to 3% failure rate and is discouraged at this time.

Intraluminal cautery alone is superior to ligation of the vas in any way, regardless of whether cautery is also used. In other words, ligation or placing a hemoclip over the vas itself is discouraged.

Interposing fascia between the cut and cauterized ends results in very low failure rates of 0.1% to 0.5%. The fascia can be closed with absorbable suture or with hemoclips. The latter are quicker and avoid the bleeding seen occasionally when placing a suture. (For an excellent discussion of various techniques, see Lipshultz and Benson [1980]. Although it is a dated article, the material remains an excellent review.)

Excision of a vas segment greater than 4 cm is 100% successful, but causes excess morbidity and leaves little possibility of reversal. Labrecque and colleagues (2002) found that excising a longer (15 mm) segment of vas did not improve recanalization rates over shorter excisions. In some settings, specimens for pathologic examination may be required by policy; however, there is little or no benefit, and substantial added cost, in having histologic confirmation. The optimal length of excised segment is thought to be 1 to 2 cm. Experienced surgeons may not remove any tissue once they are able to identify the vas in vivo with certainty, and are certain of their cautery and fascial interposition techniques. The American Urology Association has stated that sending vas segments for histologic confirmation is not necessary. Instead of sending the segments for histologic examination, some clinicians give the 1-cm vas segments in formalin to the patient and instruct him to keep the segments in a medicine cabinet, away from children, until he has had two negative semen checks. The patient can then dispose of the segments once sterility is confirmed. Considering that 500,000 vasectomies are performed each year in the United States, that each pathology specimen costs between \$150 and \$200 to process, and that some physicians put each side in separate bottles, clinicians can save the health care system \$75 million to \$150 million per year by not sending the vas segments to the laboratory! If the patient keeps the specimens, and if the vasectomy should fail (which is rare), the patient can then submit the tissue to the laboratory for evaluation, if desired.

#### **Open-Ended versus Closed-Ended**

The "open-ended" technique uses cautery only on the prostatic end of the cut vas, along with closing the fascia over that end. It differs from other techniques in that the testicular end of the vas remains unoccluded, or "open." The open-ended technique was first recommended and used more than 50 years ago. Errey and Edwards (1986) reported an improvement in postoperative complaints. The technique is assumed to minimize back-pressure on the testicle, which could be associated with long-term pain in the occasional patient (i.e., postvasectomy pain syndrome). The trade-off is that symptomatic sperm granulomas and vasectomy failure could be increased because of the open pathway from the testicle. Careful attention to proper technique of cautery and fascial interposition helps prevent failure; however, most surgeons still routinely cauterize both the prostatic and testicular ends in the belief that this "closed-ended" method is the best assurance against failure. Some surgeons use the open-ended technique only for men younger than 30 years of age on the basis that they may be more likely

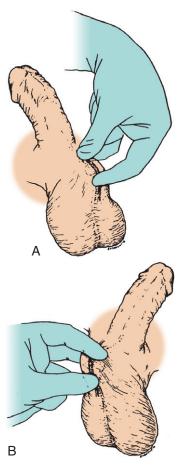

to request reversal, which would then be theoretically easier, while routinely using the closed-ended technique in those older than 30 years.

#### No-Scalpel Vasectomy Procedure

- 1. Examination and positioning of patient: Have the patient lie down undressed but draped from the waist down. As described earlier in the section on Preprocedure Patient Preparation, it is recommended that a genital examination be performed at the conclusion of the counseling process. Review those findings and, if necessary, reexamine the patient to be confident about the position and mobility of each vas. Clip any remaining excess scrotal hair.
- 2. Skin anesthesia (this step is not required with NNV): After cleaning the site with an alcohol wipe, the anesthetic may be administered before the sterile preparation and draping. Use 0.5 to 1 mL of lidocaine to raise a wheal in the median raphe. The small volume helps prevent distortion at the site of entry. Lidocaine may be mixed with sodium bicarbonate to reduce the brief burning sensation during injection. Epinephrine is generally not used in the deep injection to avoid arterial constriction. However, some physicians prefer to use lidocaine with epinephrine in the skin wheal because the area of anesthesia is later identified by the resulting blanching.
- 3. Isolating the vas with the three-finger technique: The right-handed surgeon stands at the patient's right side. The left-handed surgeon will use reverse handedness throughout. Identify the left vas in the upper third of the scrotum by palpating from the midline laterally. The vas is firm to compression and about the diameter of a cooked spaghetti noodle or a ball-point pen refill. Use the three-finger fixation method to secure the vas, as follows. Reaching across the patient, place the middle finger of the left hand (if right-handed) under the scrotum and press up from behind the scrotum, elevating the vas to the anterior surface. Press down from the front of the scrotum with both the thumb and index finger, securing the vas in place (Fig. 126-6A). The space between the thumb and index finger is where you will access the vas.

Although the vas can be occluded close to the epididymis (even in the convoluted portion), it is desirable to choose a site more distal (i.e., closer to the groin), where the straight segment of vas is more easily mobilized, less likely to spontaneously recanalize, and more amenable to surgical reanastomosis. Secure the vas then in the midline between the upper third and the lower two thirds of the scrotum.

- 4. Anesthetizing the vas: Use NNV (see earlier discussion) or the following traditional vasal block technique (Fig. 126-7): With needle and syringe, enter the skin from the anesthetized midline spot, advance the needle tip several centimeters cephalad along the vas, and inject 3 to 5 mL around the vas high on the left. If the needle tip lies very close to the vas, the anesthetic will flow around the vas, within the internal spermatic fascia, and it will effectively block the perivasal nerves without having to repeatedly insert the needle. The anesthetic effect will extend along the vas toward the epididymis without distorting the tissues where you will be dissecting the vas. Let the vas fall back, then grasp the right vas (Fig. 126-6B). Here the three-finger fixation method does not require reaching across the patient, but directly placing the left middle finger behind the right side of the scrotum to elevate the right vas, and applying counterpressure with the thumb and index finger anteriorly. Reinsert the needle through the midline, advance the tip along the right vas, and inject another 3 to 5 mL.
- 5. Surgical preparation and draping: The anesthetic will have time to take effect while the preparation is taking place. Nonsterile gloves are used with warm disinfectant solution. Warm solutions will help relax the scrotum, which allows easier palpation of the

**Figure 126-6 A,** Three-finger fixation of the left vas beneath the skin in the midline. **B,** Three-finger fixation of the right vas. (From Li SQ, Goldstein M, Zhu J, Huber D: The no-scalpel vasectomy. J Urol 145:341–344, 1991.)

vas. A 50% solution of chlorhexidine (Hibiclens) smoothes the skin during palpation of the vas, unlike the stickier povidone—iodine solutions. Prepare well down onto the perineum because the hands will often be in this area when manipulating the vas. Cover the area with sterile surgical drapes. A fenestrated drape usually goes over the scrotum, whereas a nonfenestrated drape may be placed over the thighs.

6. Fixing the vas in the clamp: Isolate the left vas using the three-finger technique described step 3. Next, use the VFF to pinch the skin to demonstrate for both you and the patient the effect of the anesthetic. (If necessary, reposition your grasp or inject more lidocaine.) Now spread the tips of the VFF approximately

4 mm and place them against the skin, straddling the vas, which is in the space between your thumb and index finger. Gradually increase downward pressure against your middle finger. Warn the patient that he will feel pressure for the next few seconds. When you feel the pressure of the two tips of the forceps distinctly on the pad of your middle finger, begin *slowly* closing the VFF. Just before locking the forceps closed, slightly relax the downward pressure, so as not to pinch the posterior scrotum, but while completely encircling the vas in the grasp of the VFF (Fig. 126-8A).

- 7. Repositioning your grasp: At this point, release the three-finger grasp and reposition your left hand to hold only the VFF in the manner shown (Fig. 126-8B). Note that there are no fingers behind the scrotum at this point. The tips of the VFF are elevating the vas and the handles are lowered.
- 8. Penetrating the skin: While holding the vas firmly fixed in position in the VFF, use the SDF with the tips spread apart to pierce the skin where it is tensed over the vas, penetrating down into the lumen of the vas with one of the tapered tips (Fig. 126-8C). This tract will be dilated to deliver the vas to the surface. So, carefully slip the single tip out of the tract, close the forceps, and reinsert the two tips while closed together to the depth of the tract.
- 9. Exposing the vas: While keeping the tips deep in the tract, spread the handles of the SDF widely to spread the tips 4 to 8 mm, dilating all layers of skin and fascia down to the vas in one step. This mode of dissection is remarkably free of bleeding compared with a layer-by-layer approach or sharp dissection using a scalpel. The vas is distinguishable as grayish-white, slightly translucent tissue with a low-sheen surface. A very shiny surface indicates the vas is still covered by a layer of fascia. In that case, pierce again and spread just the thin fascia to reveal the bare vas. It is not necessary to expose more than a few millimeters of vas to proceed with delivery (Fig. 126-8D).
- 10. Delivering the vas: Now open the sharp dissecting forceps with the curve facing down and the handles held below the level of the tips. Insert one jaw, the far tip of the SDF, into the vas just 1 to 2 mm. Using care to keep the tip buried in the vas, rotate clockwise about the long axis of the instrument. As the curve of the SDF points upward, the vas will rise through the skin (Fig. 126-8E). With the vas poised in this position, use your left hand to unlock and remove the VFF (Fig. 126-8F).

Provided that the fascia has been adequately dissected and there are no fascial adhesions from previous infections, trauma, or surgery, a bare loop of vas will slide out of the fascia. Now regrasp the vas by pinching it at the top of the loop with the VFF. Avoid encircling the vas at this point; rather, grasp into the vas tissue itself (Fig. 126-8G).

If a loop of vas does not slide out easily, replace the VFF around (vs. through) the vas once again and try removing any adherent fascia by inserting the closed SDF under the vas fascia and spreading the tips against the vas surface. Alternatively, try

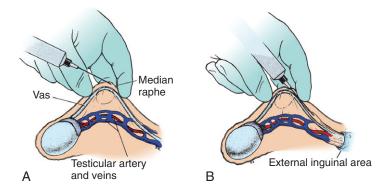

Figure 126-7 Technique of vasal block anesthesia, using the traditional syringe and needle method. **A,** To anesthetize the skin, a wheal of anesthetic is placed intradermally in the median raphe. **B,** To anesthetize the vas, the  $1\frac{1}{2}$ -inch needle is inserted through the midline wheal and advanced along the vas toward the inguinal area. The anesthetic diffuses around the vas. This is then repeated with the other vas. (From Li SQ, Goldstein M, Zhu J, Huber D: The no-scalpel vasectomy. J Urol 145:341–344, 1991.)

- passing the closed SDF or hemostat under the vas to elevate about a 1-cm section.
- 11. Baring a loop of vas: With the vas held securely, create a "window" in the "web" of fascia under the loop. Start near the top of the loop by passing one tip of the SDF through the loop, close enough to the vas that the deferential artery and all fascial vessels are cleanly separated from the vas. The artery often may not be visible, but meticulous dissection at this step will be rewarded with a bloodless field. Dilate the opening by spreading the two tips of the SDF within the loop to "strip" the tissue off about 1 cm of vas (Fig. 126-8H).
- 12. Securing the loop: A measure of safety may be added by applying hemostats to the fascia at one or both ends of the isolated vas segment (Fig. 126-81).
- 13. Accessing the vas lumen: If a segment of vas is going to be removed, hemitransect the vas but do not cut completely through, making two partial incisions 1 to 1.5 cm apart (Fig. 126-8J). If a portion of the vas is not going to be removed, the lumen of the vas may be accessed through the initial puncture of the vas if it is visible, or through an incision (Fig. 126-8K). Alternatively, the wall of the vas may be penetrated using a sharp electrocautery needle or a hot thermal cautery tip.
- 14. Cauterizing the vas: Cauterize the lumen of the prostatic end only (open-ended technique) or of both ends of the vas (closed-ended technique) by inserting the cautery tip 10 mm into the lumen, activating the cautery unit, and then withdrawing the tip (Fig. 126-8L). Whether using electrocautery or thermal cautery, the objective is to create a graduated injury to the duct lining, minimal at the upper portion and maximal at the cut tip so that fibroblasts are stimulated to form scar tissue that will occlude the vas somewhere in between. If a section of vas is excessively desiccated to the point that the muscular wall is devitalized, the entire tip may slough.
- 15. Completing transection/removing segment of vas: With the hemostats still in place, complete the transection through the entire vas. If a segment of vas is to be removed, it is placed in formalin (Fig. 126-8M).
- 16. Creating fascial interposition: With 4-0 chromic, create a pursestring closure and draw the fascia over the prostatic end of the vas, being careful that the open testicular end does not fall back into the sheath (Fig. 126-8N). Alternatively, a medium hemoclip is applied (only on the fascia). This is quicker and may cause less bleeding (Fig. 126-8O). In a similar alternative, the edges of fascia may be approximated with a hemostat and then ligated with a free tie, avoiding the use of a suture needle. Release the hemostat only from the prostatic end at this point. (There is no research evidence to conclude which side should have the fascial interposition to optimize results, or if it really makes a difference.)

**NOTE:** The suture is placed only through the fascia, not on the vas itself. Ligating the vas itself is not recommended because if it is not tight enough, the suture serves no purpose, allowing sperm to pass through. If it is too tight, the end necroses, often leaving an open tip.

17. Releasing the vas: Lower the vas into the scrotum while still grasping the fascia with one hemostat. This can reveal a bleeder that was not previously evident owing to constriction by the tight skin edges. After hemostasis is ensured, drop the vas back into the scrotum. If a bleeding point is identified at any time during the procedure, use the least amount of cautery necessary to control it. For bleeding from the vasal artery, clamp and ligate with suture or a hemoclip. Often the bleeding will be from the skin opening and not the deeper tissues, so check this area closely. In general, skin edge bleeding can be ignored until the end of the procedure, and then managed with 5 minutes of gently pinching the wound closed.

- 18. Repeat entire procedure on right side: Now identify the right vas. (If a second incision is made, provide additional anesthesia on the skin.) Isolate the right vas in the VFF. Confirm that it is the right vas by tugging gently to move the right testicle. The procedure that was carried out on the left side is now carried out on the right.
- 19. Care for the scrotal opening: The scrotal incision may occasionally require a suture if it gapes or continues to bleed from the skin edge after cautery or 10 minutes of firm pinching between gauze. A single 4-0 absorbable suture should suffice. Tell the patient to expect the suture knot to fall off after the period of absorption.
- 20. Dressing: Antibiotic ointment on the wound is optional. Several 4 × 4 gauze pads provide a loose dressing, held in place with the patient's tight briefs or an athletic supporter.
- 21. Postoperative instructions: Give the patient appropriate instructions for care. Provide two containers for semen samples, and caution the patient to use alternative birth control until the semen checks are clear.
- 22. Discharge the patient once he is ambulatory with no lightheadedness.
- Document the procedure with the appropriate operative report (Box 126-1).

Clinical photographs of the procedure are shown in Figures 126-9 through 126-11.

#### **CAUTERY INSTRUMENT STERILITY**

Sterile, disposable, single-use, battery-powered thermal cautery units are available and inexpensive for use in vasectomy. More environmentally friendly reusable units are provided with replaceable tip elements and sterile sheaths to envelop the handle.

For *electrocautery* users, sterile single-use, or reusable autoclavable handle and cord sets are available, but a clean, nonsterile cord set and handle can be safely reused, if the cord is maintained out of contact with the sterile field and the surgeon's sterile gloves. After the physician is gloved, have an assistant lower the cautery handle into a spare sterile glove by holding the cord (Fig. 126-12). Place a sterile electrode tip into the handpiece right through the glove. The handpiece can now be safely placed on the sterile tray. Reusable battery-powered units can be used in a similar fashion.

#### POSTPROCEDURE PATIENT CARE

All of this information should be discussed with the patient during the preoperative counseling session. It is important to reinforce it on the day of surgery.

No routine postprocedure office visit is necessary. For the physician who is just beginning to perform vasectomy procedures, it may be advisable to see the patients in 1 to 2 weeks to gain an appreciation for the normal postprocedure changes.

An uneventful recovery thus depends on the patient following good self-care principles and the specific written instructions he received in the office. Sample postoperative handouts can be found online at www.expertconsult.com. These sample instructions describe expected conditions and those that should prompt a call to the physician. It is always best to thoroughly review the instructions with the patient, as well as providing them in written format for later reference.

Patients usually report minimal to mild discomfort after NSV. Severe pain is rare enough that it should prompt a call to the physician. NSAIDs such as naproxen sodium (Aleve) or ibuprofen will keep most patients comfortable and may be routinely taken the day of surgery and the first day after surgery. They can be continued if the patient is feeling an ache or fullness. Some patients will simply rest easier knowing they have a prescription analgesic medication on hand, should they need it. Narcotics (rarely needed) can

#### Date The patient comes in today for a vasectomy. He understands the risks, benefits, and possible complications. He has read over the handouts and viewed the instructional tapes. All questions were answered before the start of the procedure. He does understand that alternative contraceptive choices are available and that vasectomy must be considered a permanent procedure. He has no further questions, and subsequently we proceeded. Procedure note: Procedure: Bilateral no-scalpel, no-needle vasectomy. Surgeon: John L. Pfenninger, MD Assistant: Present in the room: wife, partner, friend, family member Driver: Anesthesia: \_cc of a 50/50 mixture of 2% lidocaine with epinephrine and 1% lidocaine without epinephrine \_cc of 2% lidocaine with epinephrine using the MadaJet. Premedication: 800 mg ibuprofen Valium 10 mg

Box 126-1. No-Scalpel Vasectomy Operative Report

Patient \_

atropine 0.5 mg Dt

Complications: None or

Estimated blood loss:

Tolerance (circle one): Excellent Good Poor

The patient was laid supine and the anterior scrotum was prepped with alcohol. The left vas was grasped and 0.1 cc of 2% lidocaine with epinephrine was deposited around the vas in the upper scrotum using the MadaJet technique, in the midline. Similarly a vasal block was carried out on the right. The entire scrotum, penis, and suprapubic and inguinal areas were then prepped with Betadine. Sterile draping was carried out.

Betadine was wiped clear of the scrotum. The left vas was identified, brought to the midline, and isolated with the ring forceps. The skin over the vas was then punctured using the sharp dissecting vas forceps. A small opening was made and the perivasal tissue was stripped clear. The sharp dissecting forceps were then inserted under the vas and the ring clamp removed and replaced through the vas itself for stabilization. Dissection of the perivasal fascia was completed providing 1 to 1.5 cm of vas deferens. The vas was then hemitransected on both sides of the elevated loop. The proximal and distal ends of the vas were cauterized using the battery cautery unit. The proximal vas (testicular end) was then fully transected and allowed to retract below the fascial tissues. The fascia over the proximal vas was then occluded using a medium metal hemoclip. The clip was placed up to, but not on, the distal vas. This completed a good fascial interposition between the two ends. The distal vas end protruded above the hemoclip. The distal end was then fully transected and the tissues returned to the scrotum. The 1 cm of transected vas was placed in

Continued on following page.

#### Box 126-1. No-Scalpel Vasectomy Operative Report—cont.

formalin. Good hemostasis was noted. Attention was then turned to the right side where the vas was isolated and brought through the same midline opening. The same technique carried out. The right vas was confirmed by gently tugging the vas and noting testicular movement on the right.

After completion of the procedure, the scrotum was washed with sterile saline. Good hemostasis was noted at the skin site. Antibiotic ointment was placed over the entry wound and gauze applied. An athletic supporter was placed.

The patient was given postoperative instructions and will watch for signs of infection and report any excessive pain or bleeding. Guidelines for complete rest today with gradual increase in activity were reviewed. Acetaminophen and ibuprofen are to be used for discomfort. Ice is to be applied to the scrotum until the evening. Gauze packing should be used inside the scrotum until the morning. The athletic supporter should be used for at least 48 hours. The patient should refrain from heavy lifting, straining, running, jogging, and sexual activity for one week. He is aware that live sperm may

be present in the ejaculate for up to 15 ejaculations. It was
emphasized to use contraception until two sperm evaluations at
6 and 12 weeks show no sperm. Containers were given to the
patient and methods of collection were explained. The patient
shall keep the two pieces of transected vas in the medicine
cabinet, in the formalin jar, until the two negative semen
checks. At that time, he can dispose of them. The patient
should call if there are any other problems. Postoperative
instruction sheets were also given. Once again, the patient had
no further questions.

Changes to procedure: None or
Impression: Uncomplicated no-scalpel, no-needle vasectomy

supplement, but should not replace anti-inflammatory medication, except when the latter is contraindicated.

Most men will do better if they use a scrotal supporter ("jock strap") for a few days. These are often reinforced with gauze or a washcloth to provide more support/pressure.

Activity should be limited. The day of surgery, it is best to relax with the feet up such as in a recliner. It is permissible to go to the bathroom and to the table to eat, but otherwise the feet should be up. On the first postoperative day the patient may walk around inside the house. A cool shower is acceptable. On the second postoperative day limited activities outside the house, such as going to church, to a movie, or to a restaurant, are permitted. On the third day, most activities can be resumed, except for strenuous ones like jogging, riding a bike, weight lifting, and having sex. These should be delayed for a week. Most men can return to work and gradually ease back into their usual activities.

Be sure to reinforce that the patient must use another form of contraceptive until he has two negative semen checks at 6 weeks (after 15 ejaculations) and again at 12 weeks. Samples can be obtained by self-stimulation, collecting secretions from a condom, or withdrawing after intercourse and collecting the ejaculate. It is best to examine the specimen within 2 hours of collection.

A routine telephone call to the patient on the first or second day after the vasectomy can provide valuable reassurance, promote compliance with activity restrictions, and address any questions or concerns that might have arisen on the part of the patient or his partner.

#### **COMPLICATIONS**

#### Minor

Minor complications, causing discomfort and inconvenience but no serious threat to health, occur in 5% to 10% of vasectomy patients.

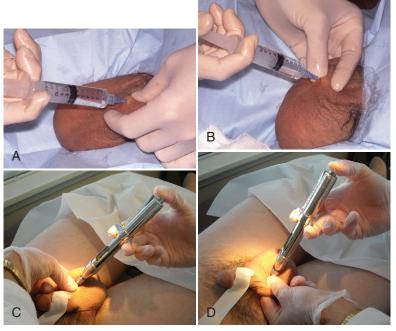

Figure 126-9 Vasectomy anesthesia: vasal block of left vas (A) and right vas (B). No-needle anesthetic using MadaJet to left vas (C) and right vas (D).

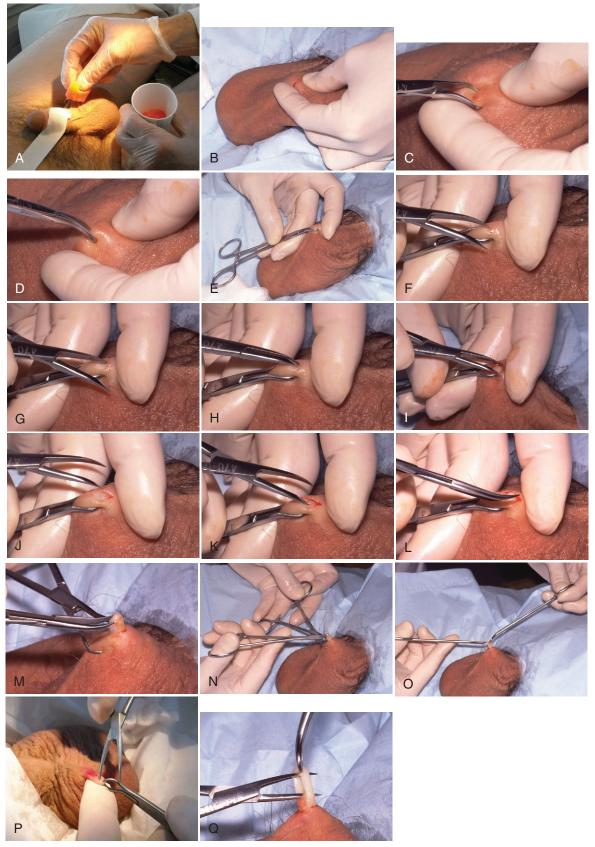

Figure 126-10 The no-scalpel vasectomy procedure. **A,** Warmed chlorhexidine (Hibiclens) preparation. **B,** Three-finger grasp of left vas. **C,** Straddling left vas with vas-fixing forceps (VFF). **D,** Vas is securely fixed in place with the VFF. **E,** Regrasping the VFF, the handles are lowered and skin is tensed over the prominent segment of the vas. **F,** Sharp dissecting forceps (SDF) poised over vas. **G,** SDF tip in the lumen of vas. **H,** Both tips now in lumen. **I,** Spreading all layers, skin to vas, in one motion. **J** and **K,** The SDF tip is placed into the lumen. **L** and **M,** The hand is rotated palm up, so the SDF tip hooks and delivers the vas. **N,** The VFF is unlocked and released. **O,** The vas loop is then regrasped. **P,** The fascia is sharply dissected from loop. **Q,** Fascia is stripped from a bare loop of vas, allowing occlusion to proceed with no bleeding from the plethora of fascial vessels.

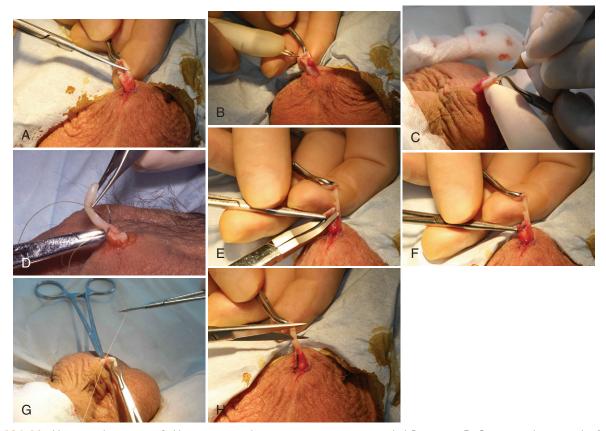

Figure 126-11 Various occlusion steps. **A**, Hemitransecting the vas in two areas approximately 1.5 cm apart. **B**, Cauterizing the two ends of the hemitransected vas. (In the open-ended technique, only the prostatic end would be occluded.) Here, a battery cautery unit within a sterile glove is being used. **C**, Intraluminal electrocautery. The sharp tip has penetrated the vas wall and 1 cm of the needle electrode lies within the lumen before the current is applied and the electrode is gradually withdrawn. **D**, Fascial interposition may be accomplished using a pursestring suture to close the edges of the fascial opening. **E**, Here the fascia is approximated with a hemostat, covering over the vas end. A hemoclip is then applied to secure fascial closure. **F**, Note the hemoclip does not include the vas. **G**, Alternatively, the fascial closure is secured with a free tie. **H**, Excising the segment of vas by completing the other hemitransection. (**A**, **B**, **E**, **F**, and **H**, Courtesy of Jan Drlik, MD, The Medical Procedures Center, PC, Midland, Mich.)

- Swelling and discomfort are prevented routinely by using an ice pack, mild analgesic (acetaminophen or ibuprofen), a tight athletic supporter packed with gauze or a wash cloth, and bed rest. The ice is usually placed over the supporter but may need to be applied directly to the skin if bleeding is suspected.
- Bleeding from the skin incision is normally nil or less than a 3-cm spot on the gauze overnight. Persistent bleeding is controlled with pressure by pinching the skin incision between gauze for 10 minutes
- Ecchymosis, a purple discoloration, makes the scrotum look bad but is harmless. Careful cautery of any bleeding, especially on the skin margins of the incision, usually prevents it. Ecchymosis may become extensive, involving the entire scrotum, and can extend to the penis and even to the groin and thighs. It may present in the first day or several days later. It will be alarming to the patient, but in the absence of a hematoma (see later discussion), ecchymosis is harmless and usually painless and results from minor amounts of blood extravasated into the skin or subcutaneous layers. The color may evolve through red, yellow, and green as the blood is resorbed. Prevention is by meticulous hemostasis. Icing the area intermittently during the first day may be effective.
- Superficial wound infection is rare because of the excellent blood supply to the scrotum. A minimal infection responds to local treatment and oral antibiotics. The key to prevention may lie in dissuading the curious patient from touching the wound.
- Skin reaction to the surgical antiseptic solution may present with rash and itching.

- Neuroma is a tender nerve ending buried in scar tissue, where a small sensory nerve was severed or damaged. It is rarely reported after vasectomy and is more often a curiosity than a hindrance to normal activities. A single injection of procaine combined with an equal dose of reassurance can provide a definitive cure.
- Suture rejection can present weeks after vasectomy. Absorbable plain gut suture may prove the least reactive for fascial closure.
- Hemospermia occurs very rarely in the first few months after vasectomy. It clears up spontaneously and has no clinical significance.
- Sperm granuloma is a reaction to sperm leakage into the tissue at the site of the vas division or a rupture in the epididymis. Although such leakage is common, only about 1.5% of patients report finding a tender nodule there. Treatment is an NSAID and reassurance. Rarely, the nodule will require excision or injection with steroids. Abstaining from sexual stimulation in the first week is thought by some to reduce the incidence of sperm leaking from an unhealed vas, but data are lacking on the question. Patients with open-ended vasectomy do not present more frequently with this complaint, suggesting that leakage and scarring are not factors.
- Congestive epididymitis usually presents with a new, unilateral, or
  occasionally bilateral, tenderness and achy pain localized to the
  epididymis and radiating to the ipsilateral groin, aggravated by
  movement. It can occur weeks or years after the procedure. The
  epididymis feels enlarged and boggy to palpation and may be
  somewhat tender. It is self-limited, but may linger for 1 to 3 weeks

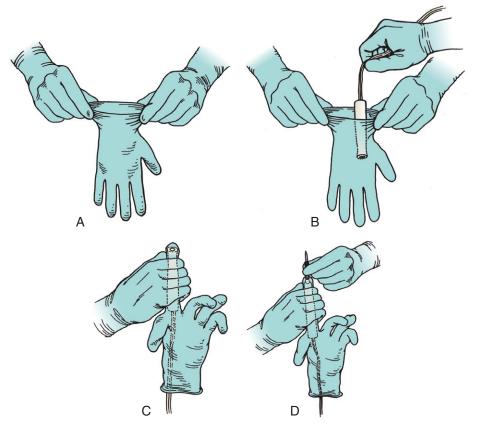

Figure 126-12 Maintaining a sterile cautery instrument. **A,** Gloved physician holds the sterile glove. **B,** Assistant holds the cautery handpiece without the tip by the cord and carefully drops it into a finger of glove. **C,** Gloved physician grasps the cautery handle inside the glove finger. **D,** Sterile tip is punctured through rubber glove. The unit can now be handled in a sterile fashion; the clinician is careful not to contaminate the surgical field with the cord. (If it is a battery unit without wire, the unit can be activated so that the tip will burn through the glove to be exposed for use.)

if untreated. It responds within 48 hours to a full regimen of NSAIDs, such as naproxen sodium 1100 mg per day or ibuprofen 800 mg three times a day, and sexual abstinence for 10 to 14 days.

- Postvasectomy pain syndrome is a term applied to various types of chronic pelvic and scrotal pain in men who have previously had a vasectomy. The incidence is low and, in most cases, the symptoms eventually abate spontaneously. Its causation and relationship to vasectomy and to chronic pain that occurs in men without vasectomy are unknown. Management may be enhanced by a supportive, multidisciplinary approach including urologic evaluation, psychological support, and pain clinic management of medications and therapies (an extremely rare occurrence). Surgery has provided little if any benefit to patients with postvasectomy pain syndrome.
- Persistent sperm in the ejaculate. Depending on the study and technique used, vasectomy failure rates vary from 1/100 to 1/1200. The latter efficacy is obtained by using resection of 1 cm of vas, cautery of the ends, and fascial interposition. Most often failure is due to the process of spontaneous recanalization, by which a channel forms between the cut ends of a vas and conducts fresh sperm from the testicle. If recanalization occurs, it generally takes place in the first few weeks after surgery and is detectable by routine semen testing (see later discussion). In half of those cases the channel will close permanently and sperm will disappear from the semen as the scar around the vas matures. If motile sperm persist over time, however, a repeat vasectomy is performed on each vas.
- If a true surgical failure is suspected based on semen analysis, it
  may be advisable to have the patient produce a specimen in the
  office before proceeding with repeat vasectomy. However, genetically proven paternity has occurred with men whose semen tests

- were clear of visualized sperm both before and after impregnation. Couples dealing with unexplained postvasectomy pregnancy should be made aware of such rare possibilities.
- One of the most common causes of persistent sperm in the ejaculate is *not having had at least 15 ejaculations before the check*. Sperm that may have refluxed into the prostate and seminal vesicles can persist for 8 to 10 weeks or more.
- Misidentification of one or both of the vasa deferentia (very rare)
  could be detected by submitting excised specimens for histologic
  examination by a pathologist. This is advisable when any doubt
  exists at the time of surgery. However, when gross tissue identification is certain, histologic examination is not cost effective and
  does not provide assurance against failure.
- Despite hearsay evidence of vasectomies failing because of a third vas deferens, documented cases of supernumerary vasa are extremely rare.
- Prematurely abandoning other contraceptive methods before achieving a clear test can result in pregnancy with a successful vasectomy as well as with a failed vasectomy. If two clear semen checks are obtained (no sperm seen), the incidence of late (secondary) failure is very rare, and pregnancy risk is even lower.

#### Major

Major complications, which cause temporary disability and require medical or surgical intervention, occur in less than 1% of patients and include scrotal hematoma and infection.

 Hematoma is a mass of blood accumulated in the scrotum from a leaking blood vessel. It is a major concern because the loose connective tissue of the scrotum may allow a hematoma to expand

Figure 126-13 Left hemiscrotal hematoma postvasectomy.

from a few centimeters to the size of a grapefruit (Fig. 126-13) Thus, early (nonsurgical) intervention is critical. It is generally not possible to apply direct pressure on the site of internal bleeding, but the supporter can be packed tight with gauze or a washcloth. Strict bed rest, elevating the scrotum on a folded towel, and applying ice packs intermittently (30 minutes on and 15 to 20 minutes off to prevent injury) will usually stop progression. Attempts at surgical evacuation may be unwise because clots are not easily extracted and surgical trauma to neurovascular structures may contribute to excess morbidity. Close monitoring for signs of infection is combined with progressive mobilization with scrotal support. Complete resolution may take from several weeks to many months. Prevention is by meticulous surgical hemostasis during the surgery and by limiting patient activity after surgery. With the current NNV methods, patients feel so good after surgery that they tend to overdo it. Proper postoperative rest and care cannot be stressed enough.

Scrotal infection after vasectomy is a rare but potentially serious complication. Fever, chills, redness, warmth, swelling, and induration are signs of infection. Prompt evaluation and early consultation are important. Very localized signs around the incision with an otherwise negative scrotal examination and no systemic symptoms might safely be treated on an outpatient basis with oral antibiotics and warm packs if careful observation for progressive symptoms and follow-up within 48 hours is ensured. Signs of cellulitis or the presence of systemic symptoms would usually warrant parenteral antibiotics. If fluctuance is detected, surgical drainage of an abscess should not be delayed. Preexisting skin infections, diabetes mellitus, and immunodeficiency contribute to risk of infection. Careful attention to sterile technique is essential to prevention. Also important is reducing tissue trauma in surgery by handling tissues gently, minimizing cautery and suture ligation, and using atraumatic forceps. Early recognition and careful evaluation of symptoms are keys to correct diagnosis. A low threshold for hospitalization and for parenteral antibiotic use to arrest an infection may prove critical to management of resistant infections.

Regardless of one's surgical skills, some complications cannot be avoided. The most important thing is to be prepared to handle them properly so as to minimize the adverse effect on your patient.

Be sure patients know to call you if symptoms arise, and ensure that you or someone equally knowledgeable is available to take their calls.

Stay in touch, providing open communication that is compassionate, informative, and honest. Even when a consultant is making treatment decisions, be sure to stay involved and obtain information on your patient. Contribute to his care through active listening and ensuring his needs are met. He should know that you care about his recovery. Even a patient who has a good outcome may become resentful and litigious if he feels neglected or uncared for. On the other hand, a patient who has suffered a major complication may advocate for his physician if he feels genuinely well cared for throughout the experience. Remember, too, the common wisdom that one patient's unhappiness can have widespread repercussions with other men considering vasectomy in the community.

In large, long-term studies of vasectomy, *no increase* in mortality or incidence of *chronic disease*, including, among other entities, hypertension, diabetes, autoimmune diseases, cardiovascular diseases, and prostate cancer, has been found. There is no decreased libido or sexual experience. Basically, what is present before the procedure will persist after the procedure.

Studies show patients are 98% to 99% satisfied with the vasectomy decision. However, some *regret* having the procedure, either because of the complications discussed previously or later desire for children.

#### POSTOPERATIVE SEMEN TESTING

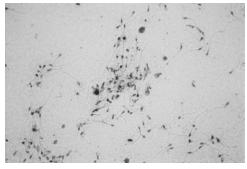

A postoperative semen check is a waived CLIA (Clinical Laboratory Improvement Amendments) test. It is customary to require two postprocedure semen tests. Because sperm can persist in the ejaculate for many weeks, the first specimen is tested after 6 weeks or 15 ejaculations (whichever is later) and the second after 3 months.

Allow the freshly collected semen specimen to stand at room temperature for 30 minutes (or 10 minutes at body temperature) until the viscous mucus component is autolyzed by enzymes in the semen. The clinician places a drop of unspun fresh ejaculate onto a slide (no staining is necessary). The sample is covered with a coverslip and examined under high power (40× magnification) for the presence of live or dead sperm (higher power with oil immersion is not necessary). Figure 126-14 shows the appearance of many sperm in one high-power field in a *failed* vasectomy (no sperm should be seen).

Some define a positive specimen as having any visualized sperm under high power (unspun specimen). Sequential semen testing in a study of 364 patients showed that a single sample with "severe oligospermia" (<100,000 sperm/mL) at 12 weeks predicted success of vasectomy with 99.7% accuracy. That would correspond to seeing approximately one sperm per high-power field using the aforementioned technique. Observing live sperm after 6 weeks suggests, however, that a second specimen should be examined.

**NOTE:** The author's approach is to require that a single specimen pass an examination of 100 high-power fields with no more than 2 sperm seen (approximately 10,000/mL) and no motile sperm. Specimens are accepted up to 24 hours after collection to improve patient compliance. The editor prefers two samples at 6 and 12 weeks. A few dead sperm are acceptable at 6 weeks but usually are not seen. If any sperm persist at 12 weeks, another sample is requested. Any live sperm after 12 weeks should be regarded as a possible failure. Unprotected intercourse is allowed after the two negative checks.

An early pregnancy does not mean a failed surgical technique. Pregnancy can occur either because contraception was not used until the sperm were cleared or because of spontaneous recanalization in spite of proper technique.

**Figure 126-14** Postoperative semen check: the appearance of sperm in the ejaculate of a failed vasectomy. (Courtesy of Nicholas Hruby, MD, Saginaw, Mich.)

Semen tests are included as part of the vasectomy procedure code (55250) if performed in the physician's office. (They are separately billable if performed by an independent laboratory.)

#### **REVERSAL**

With fully informed consent, patient and partner satisfaction with vasectomy is extremely high. (Rosenfeld and colleagues [1993] showed it is the only contraceptive method with which 100% of women are satisfied. For tubal ligation, the method with next-highest acceptance rate, only 78% of women are satisfied.) Occasionally, however, patients request vasectomy reversal, usually because a new partner wishes to have children. Reversal can be accomplished using either a macroscopic or microscopic approach, and results in pregnancy approximately 50% to 80% of the time. The sooner it is reversed, and the longer the testicular remnant of the vas, the better the chances of reversal. Observation of live sperm from the testicular vas end at the time of surgery is another good prognosticator. Although patency is often achieved, the presence of sperm antibodies that persist after reversal can inactivate sperm efficacy to impregnate the egg. Intracytoplasmic sperm injection can be used, but is much more costly. The use of previously frozen sperm is the least expensive option, if available (see Chapter 123, Sperm Banking).

#### **PATIENT EDUCATION GUIDES**

See the following forms online at www.expertconsult.com:

- Patient Consent
- Patient Education
  - Preoperative
  - Postoperative
  - Postsedative
  - Worksheet
- Vasectomy Questionnaire

#### **CPT/BILLING CODES**

55250	Vasectomy, unilateral or bilateral (separate procedure),
	including postoperative semen examination(s)
89321	Semen analysis, presence and/or mobility of sperm (if
	vasectomy performed elsewhere)
99203	Counseling visit(s), new patient
99214	Counseling visit(s), established patient

Other routine office visit codes can also be used for the counseling sessions.

# PREGNANCY TERMINATION: FIRST-TRIMESTER SUCTION ASPIRATION

Lawrence Leeman • Emily Godfrey

First-trimester surgical termination of pregnancy (suction aspiration) is one of the safest surgical procedures performed in the United States, with 1.2 million procedures performed each year. By the time a woman reaches 45 years of age, approximately one in three will have had an abortion. About half of these are performed at 8 weeks or less in gestational age, and 88% are completed in the first trimester of pregnancy. Although abortion has been legal in all 50 states since the 1973 Roe v. Wade Supreme Court decision, many states have imposed laws such as parental consent for minors, mandatory waiting periods, and compulsory state-directed counseling that may limit availability of the procedure or discourage a woman from having an abortion. Therefore, clinicians performing abortion must be aware of any state and local restrictions that govern it.

Virtually all first-trimester surgical abortions are accomplished with vacuum aspiration. This chapter contains specific information about uterine aspiration using manual vacuum aspiration (MVA) and electric suction abortion in the first trimester. The most commonly used MVA device is a 60-mL syringe with locking valves and a plunger that provides identical suction pressure (26 inches of mercury) as an electric pump until the cylinder reaches approximately 80% capacity. The aspirator can be quickly emptied and reused if more capacity is needed. It is small, portable, and quiet and thus very practical for a variety of settings, including offices, emergency departments, and hospital-based locations. Although there is still some suction sound, there is no mechanical noise. When MVA and electric suction have been compared in studies, some patients prefer MVA because the sound of electrical suction can be disquieting. Clinicians may prefer MVA for aspiration at early gestational ages because it causes less disruption of the gestational sac, the presence of which confirms a successful aspiration procedure. Electrical suction may be preferred for later first-trimester gestational ages because of the larger amounts of products of conception (POC) and the need for repeat passes if MVA is used.

The suction technique described in this chapter for first-trimester abortion can also be used for surgical completion of spontaneous abortion, including missed and incomplete abortion. Many institutions use operating room settings for completion of spontaneous abortion. In most circumstances, however, spontaneous abortion treatment can be integrated into outpatient settings. Expectant management to await spontaneous passage of the POC and medical management with misoprostol are also safe options. The highest patient satisfaction is achieved when patients can make their own choice of a management plan. The relative and absolute contraindications to first-trimester abortion would also apply to treatment of spontaneous abortion.

#### **ANATOMY**

Anatomic variations can increase the likelihood of complications occurring during uterine aspiration. A *vaginal septum* may interfere with visualizing and accessing the cervix. *Cervical stenosis* may occur and can be caused by prior surgical procedures including loop electrical excision, cryotherapy, and cold knife cone biopsy. Dilation may be more difficult in *nulliparous* teenagers because of a tight cervical os, particularly at early gestational ages. *Mullerian anomalies* including uterus didelphys, bicornuate uterus (Fig. 127-1), and an intrauterine septum may interfere with successful uterine aspiration. Intraoperative ultrasonography can facilitate the procedure. *Adnexal masses or uterine fibroids* may result in inaccurate gestational age dating; fibroids can interfere with cervical dilation.

#### **INDICATIONS**

- Elective abortion up to 12 weeks' estimated gestational age
- Treatment of early pregnancy failure or spontaneous abortion for uterine sizes up to 12 weeks
- Postabortal hematometra
- Backup for medical abortion (mifepristone/misoprostol or methotrexate/misoprostol; see Chapter 128, Pregnancy Termination: Medication Abortion)

#### **CONTRAINDICATIONS**

Medical contraindications are rare. It is important for clinicians to be aware that some clinical scenarios require stabilization before abortion or that the procedure be performed in a hospital setting.

#### **Absolute**

Absolute contraindications to first-trimester abortion in an outpatient setting include the following:

- Hemodynamic instability
- Active pelvic infection

#### **Relative**

Relative contraindications include the following:

- Uncontrolled hypertension
- Uncontrolled diabetes
- Molar pregnancy (based on gestational age)
- Coagulopathy

**Figure 127-1** Ultrasonographic scan of bicornuate uterus with gestational sac in the right horn.

#### **EQUIPMENT AND SUPPLIES**

- Medium Graves speculum (size and type varies based on patient habitus).
- Single-tooth or atraumatic tenaculum.
- Syringe with 22- to 27-gauge, 3-inch spinal needle, or 22- to 27-gauge needle on 3-inch needle extender.
- Anesthetic agent for cervical block (e.g., 0.5% or 1% lidocaine with epinephrine or vasopressin).
- Rigid cervical dilators for mechanical dilation: Pratt, Hegar, or Denniston (see Chapter 136, Cervical Stenosis and Cervical Dilation).
- Osmotic dilators: Sterilized seaweed stem (Laminaria japonicum) available in a variety of sizes (2 to 10 mm); when used, they should be inserted into the cervical os 6 to 18 hours before the procedure (see Chapter 136, Cervical Stenosis and Cervical Dilation).
- Cervical softening agents: misoprostol (prostaglandin E<sub>1</sub> analog), available in 200-µg dose.
- Povidone-iodine or other antiseptic solution or sterile water.
- Ring forceps.
- 4 × 4 gauze pads.
- Manual vacuum syringe (Ipas MVA Plus; Fig. 127-2).
- Disposable suction cannulas, which come in a variety of sizes or flexibility, including flexible, semiflexible, or rigid (curved and straight; see Fig. 127-2). It is essential that the clinician identify which cannula produces adequate seal and suction with the type of MVA device that is being used.
- Suction machine with tubing as an alternative to MVA syringe (Fig. 127-3).

**Figure 127-2** Ipas Plus syringe with flexible plastic cannulas for manual vacuum aspiration. (From ARHP [Association of Reproductive Health Professionals]: www.arhp.org.)

Figure 127-3 Berkeley Synevac vacuum curettage machine.

- Metal bowl for POC (if using MVA)
- Medium-sharp uterine curette
- Formalin jar (POC may be sent to pathology; however, many physicians performing aspiration abortion examine their own POC)
- Intravenous solutions, tubing, and oxytocics (for treatment of excessive bleeding)

#### **PRECAUTIONS**

With the availability of portable office ultrasonography, pregnancies can be detected at very early gestational ages. In the past, women were frequently asked to defer pregnancy termination until they were at least 7 weeks' gestation, when a change of uterine size can be detected on physical examination and cervical softening occurs naturally. Now that these pregnancies can be verified earlier with ultrasonography and cervical softening agents are available, women can routinely be offered uterine aspiration or medical abortion as soon as a gestational sac is identified on transvaginal ultrasonography. Women who present for a first-trimester abortion with a positive urine pregnancy test in whom ultrasonography cannot confirm an intrauterine pregnancy can pose a management dilemma. In these cases, an algorithm has been suggested by Creinin and Edwards (Fig. 127-4). Outpatient uterine aspiration under local analgesia with a cervical block works well for most women. Some women, including those with a history of anxiety disorder, substance abuse, or poor tolerance to gynecologic examinations may be best cared for in clinical sites where conscious sedation or general anesthesia is provided. These patients should be identified during options counseling and offered referral to a clinic that can offer a greater range of anesthetic options.

#### PREPROCEDURE PATIENT EDUCATION

It would be impossible provide a full discussion of counseling here, but several techniques and general principles can be outlined.

 Explore the patient's feelings. This may be done by asking nonjudgmental and open-ended questions as well as through active listening. The clinician should empathize and help the patient

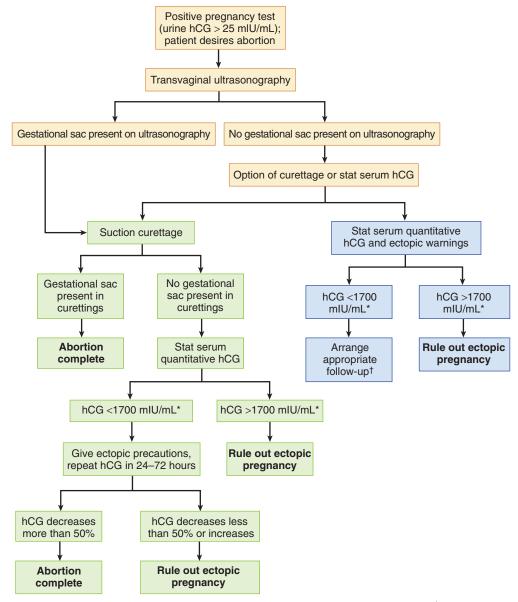

Figure 127-4 Algorithm for early surgical abortion. hCG, human chorionic gonadotropin. \*Discriminatory zone. †The timing of follow-up serum quantitative hCG test or ultrasonography (or both) may vary according to patient's risk factors for ectopic pregnancy. (Adapted from Creinin MD, Edwards J: Early abortion: Surgical and medical options. Curr Probl Obstet Gynecol Fertil 20:1–32, 1997.)

reflect on her own feelings. Ambivalence should be acknowledged and discussed.

- 2. Explore options. The patient's options regarding her pregnancy include terminating or continuing the pregnancy. If she chooses to continue the pregnancy, she has the additional option of parenting or making an adoption plan. The risks, advantages, and disadvantages of each option should be explored in the context of the woman's particular life situation. If she chooses pregnancy termination, appropriate options based on gestational age should be discussed.
- 3. Making decisions. Strategies for decision making and the need for any additional counseling may be explored. The patient should be encouraged to seek advice from others she trusts: partner, parents, siblings, friends, teachers, or spiritual counselors. It is imperative that a timetable for decision making be established based on the gestational age.
- 4. Screening for special problems. Extreme anxiety, ambivalence, drug or alcohol use, medical problems, or psychological problems may require special and individualized measures.

- 5. Informed consent. The risks of the procedure must be reviewed and any questions answered. The patient's ability to give informed consent must be reviewed with regard to her age, mental status, and any possibility of coercion. A support person may be present during any procedure.
- 6. Postprocedure issues. These include the need for any additional counseling, contraception, follow-up visits, and reporting any complications. Emerging evidence indicates that increasing use of contraceptive implants and intrauterine devices (IUDs) could reduce repeat pregnancy among adolescent mothers and repeat abortions among women seeking induced abortion. IUDs can be inserted immediately after a first-trimester surgical abortion.

#### **PROCEDURE**

Before starting the procedure, the following steps must be completed:

1. Pregnancy must be confirmed. A home pregnancy test may not have been performed correctly, and therefore it is best to

- confirm a pregnancy with an in-office urine pregnancy test or ultrasonography demonstrating an intrauterine pregnancy.
- 2. Gestational age must be determined. This can be accomplished by correlating weeks from the last normal menstrual period with a pelvic examination to size the uterus. Abnormal bleeding in pregnancy, contraception use, menstrual irregularities, and poor recall of dates, denial, and even the possibility of falsification may hinder a clinician in calculating an accurate gestational age from historical data. A pelvic examination to size the uterus requires practice and may be complicated when a patient is obese or uncooperative, has uterine fibroids or adnexal masses, or has a retroverted uterus. As a rough guideline, up to the sixth week of pregnancy, the uterus is the size of a plum in nulliparous women and the size of a pear in parous women. By 8 to 9 weeks the uterus is the size of a small orange but is softer and often asymmetrically enlarged. By 10 weeks the uterus is the size of a medium orange. By 12 weeks the uterus is as large as a grapefruit and becomes palpable suprapubically in thin or normal-weight women. A retroverted uterus will pop forward out of the pelvis between 12 and 13 weeks. By 15 or 16 weeks the uterus is the size of a cantaloupe. Ultrasonographic examination is highly accurate in dating a pregnancy, regardless of historical data or results of the physical examination. Ultrasonography also sheds light on several important complications of pregnancy such as first-trimester fetal demise, ectopic pregnancy, and gestational trophoblastic disease or molar pregnancy. Many clinicians routinely perform a dating ultrasonographic examination before planning abortion by uterine aspiration. Ultrasonography can also be useful during or after the procedure to confirm completion of the procedure. Intraoperative ultrasonographic guidance is recommended for women with uterine anomalies or fibroids. It can also be used if the clinician has difficulty with dilation or uterine aspiration.
- 3. Perform a hematocrit or hemoglobin if there is a history or clinical suspicion of anemia.
- 4. Optional testing, depending on patient risk factors, the nature of the practice, and financial considerations, includes wet prep, Papanicolaou smear, gonorrhea and chlamydia screening, and blood tests for syphilis and human immunodeficiency virus.
- 5. Determine Rh factor status (mandatory). Rh-negative women who have been pregnant less than 13 weeks should receive a 50-µg dose of D immunoglobulin (MICRhoGAM 50 µg) within 48 hours of the procedure. It is ideally given during the procedure or immediately after. Some give the MICRhoGAM injection intracervically at the anterior lip where the cervical block was placed.
- 6. Premedication is recommended 30 to 60 minutes before the procedure with a nonsteroidal anti-inflammatory medication such as ibuprofen 600 to 800 mg orally. Diazepam (5 or 10 mg) or an oral narcotic may be given an hour before the procedure in selected cases.
- 7. Establishment of an *intravenous (IV) line generally is unnecessary* in an outpatient setting. Oxytocin, methylergonovine (Methergine), and other injectable drugs must be readily available should an unexpected hemorrhage occur. They can be administered intramuscularly when an IV line is not in place.
- 8. Conscious sedation may be offered. It is important that clinicians be aware of the rules and regulations regarding conscious sedation at their institutions before instituting this level of care. A simple and effective regimen is midazolam (Versed) given IV at the rate of 1 mg/min up to 5 mg, accompanied by fentanyl 50 to 100  $\mu$ g IV. The patient should be monitored for respiratory depression with a pulse oximeter and frequent vital signs, and a crash cart should be available (see Chapter 2, Procedural Sedation and Analgesia).
- Atropine 0.4 mg may be given IV or subcutaneously in patients with a history of a vagal reaction to prior cervical manipulations

- (e.g., bradycardia, fainting/loss of consciousness, diaphoresis, nausea).
- 10. Prophylactic antibiotics are a standard of care. A common regimen is doxycycline 100 mg twice daily for 3 days. Metronidazole (500 mg orally, twice daily for 2 days) is an option if the patient is allergic to doxycycline. Special consideration must be given to women with active infections, cardiac defects, prostheses, and other high-risk conditions (see Chapter 221, Antibiotic Prophylaxis).

#### **Initial Steps**

- 1. Position the patient in the dorsal lithotomy position using stirrups. The patient should have her buttocks at or slightly beyond the edge of the table.
- 2. If not already done, assess the shape, size, and position of the uterus by performing a bimanual examination.
- 3. Remove osmotic dilators, if placed previously.
- 4. After inserting the speculum, cleanse the cervix with sterile water or other antiseptic solution such as povidone–iodine.

#### Paracervical Block

 Paracervical block (see Chapter 173, Paracervical Block, for additional information) is a simple, safe, and effective means of providing local anesthesia for abortion in the office setting (Fig. 127-5). The technique can vary, including the site of injection, type of anesthetic, and quantity of solution injected. Most clinicians limit the total amount of 1% lidocaine injected to 20 mL (or 0.5% lidocaine to 40 mL) to avoid lidocaine toxicity.

#### **Cervical Preparation**

The cervix may be dilated mechanically with plastic or metal dilators, or with the assistance of preprocedural prostaglandins such as misoprostol. Prostaglandins cause softening and dilation of the cervix as well as some uterine cramping. Misoprostol is the prostaglandin of choice because it is inexpensive, stable at room temperature, and effective in a variety of dosing routes, and has been shown to be

**Figure 127-5** Paracervical block technique. "X" marks the locations where submucosal injections can be made. Ten milliliters of local anesthetic (1% lidocaine or 2% chloroprocaine) are injected with a 22-gauge needle into four sites at the 3, 5, 7, and 9 o'clock positions. (Some clinicians prefer to inject in the 4 and 8 o'clock positions only.) Ideally, the injection should be given submucosally, near the junction of the cervix and vagina. The injection should be superficial enough to raise a bleb or wheal under the mucosa. Because the area is vascular, care must be taken not to inject the anesthetic directly into a vessel. The tenaculum may be used to elevate the cervix and hold it to either side for better exposure of the injection sites.

**Figure 127-6 A,** Insertion of the laminaria. **B,** Immediately after insertion. **C,** Twelve to 24 hours after insertion.

effective in first-trimester abortion. Several studies show that misoprostol, given vaginally, is more effective than given orally; buccal and sublingual dosing have also been documented as effective, but they both have more unwanted side effects than the vaginal route. Studies examining various doses found that 400  $\mu g$  (vaginal or sublingual) is most effective and that higher doses were not necessary. Although not well studied, 400  $\mu g$  by the buccal route is a commonly used alternative. Optimal dosing occurs when misoprostol is given 2 to 4 hours before the procedure; however, administration as late as 1 hour before the procedure can be helpful with cervical softening. Patients commonly experience some cramping and bleeding before the actual surgical procedure with this drug.

Laminaria is an option for dilation but it is less popular because it requires two visits to the office (Fig. 127-6). Some clinicians routinely use misoprostol for all women undergoing uterine aspiration in the outpatient setting regardless of gestational age. Other providers prefer laminaria for primiparous women over 10 to 12 weeks and multiparous women with an estimated gestational age of 12 weeks or greater. The Society of Family Planning guidelines for first-trimester abortion state that cervical ripening be considered for all adolescents and is recommended for any women at 12 to 14 weeks or if an initial attempt at dilation has been unsuccessful.

#### "No-Touch" Technique

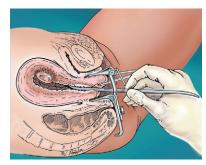

Bacteria invariably contaminate the vagina and perineum during outpatient uterine aspiration procedures despite attempts at cleansing with povidone–iodine or other preparations. The operator's fingers are likely to become contaminated from the vagina and perineum during the introduction of the speculum despite the use of sterile gloves. The "no-touch" technique is based on the operator not touching the parts of the instruments that will enter the cervix. The dilators are grasped only in their midportion (Fig. 127-7), the cannula tip is not touched, and care is taken to prevent instruments that have been used from contaminating unused instruments.

#### Mechanical Dilation with Surgical Dilators

- 1. Apply a single-tooth tenaculum to the anterior or posterior cervical lip.
- 2. Gradually open the cervix by introducing progressively larger dilators (Fig. 127-8). Hold the dilator with a delicate pencil grip, in the middle of the dilator, using the no-touch technique.

Figure 127-7 A Denniston dilator held using the "no-touch" technique.

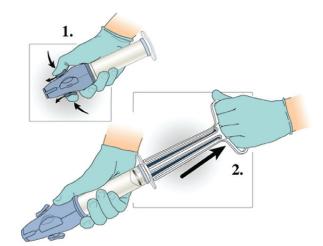

**Figure 127-8** Dilation is needed when the cervical canal will not permit passage of a cannula of the appropriate size. (From ARHP [Association of Reproductive Health Professionals]: www.arhp.org.)

- Pull gently on the cervix using the tenaculum to straighten out the endocervical canal while moving instruments into the uterus.
- 4. Apply enough pressure to move the dilator forward through the os and feel for a slight "pop" or giving sensation as the dilator passes through the internal os (see Fig. 127-8). Sometimes this sensation is not present if the patient has already undergone cervical ripening with misoprostol or laminaria.
- 5. Each dilator should be left in place for a few seconds before going to the next larger one.
- 6. Dilation is complete when the size of dilator matches the intended size of curette. Many clinicians prefer a cannula size with the millimeter diameter equal to or one size smaller than the gestational age of the patient. For example, if the patient is 9 weeks gestational age, an 8- or 9-mm cannula is used. Most patients experience some cramping during dilation.

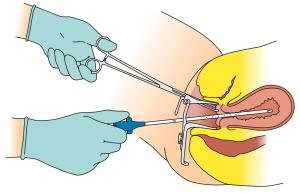

#### **Manual Vacuum Aspiration**

A key component of MVA is the preparation and use of the syringe (Fig. 127-9).

- 1. Place the cannula into the cervical os of the uterus (Fig. 127-10). Take care to maintain the no-touch technique by touching only the end of the cannula that attaches to the aspirator, being careful not to touch the tip of the cannula with hands, the perineum, or the vagina.
- 2. With the Ipas-type MVA, suction is created by first pushing the buttons on the unit down and forward (see Fig. 127-9[1]).

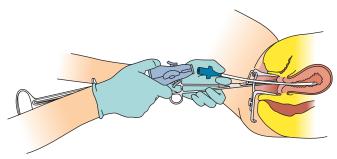

**Figure 127-9 I**, Begin with the valve buttons open and the plunger pushed all the way into the barrel. Close the valve by pushing the buttons down and forward until they lock into place. **2**, Pull the plunger back until its arms snap outward over the end of the syringe barrel. Make sure the plunger arms are positioned over the wide edges of the barrel. (Adapted from images of lpas [www.ipas.org].)

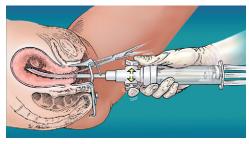

**Figure 127-10** The cannula is inserted through the cervix with traction on the tenaculum to straighten the endocervical canal. (Adapted from images of lpas [www.ipas.org].)

- 3. Draw back the plunger using a moderate amount of force to create the vacuum, until the wings of the plunger spring outward over the end of the syringe barrel (see Fig. 127-9[2]). This preserves the vacuum until the valve is opened.
- 4. Attach the aspirator to the cannula that has been placed into the uterus (Fig. 127-11).
- 5. Releasing the buttons in a backward direction activates the vacuum (Fig. 127-12).
- 6. Uterine aspiration is performed by holding the cylinder of the MVA device and using a combination of quick rotation and gentle back-and-forth movements (Fig. 127-13).
- 7. Watch the tissue that appears in the cannula and MVA cylinder to confirm correct cannula placement. Frequently, clear fluid is noted initially, followed by light tan, "fluffy" material, which is the remnants of the placenta and decidua mixed with blood. The appearance of abnormal tissue (such as omental fat or bowel) in the cannula is a sign of *perforation*. Absence of tissue is also important to note.
- 8. Withdraw the cannula and break suction to clear tubing. Empty the contents of the MVA cylinder into a metal bowl or emesis basin. The MVA device is emptied by pushing the plunger down through the cylinder.
- 9. The cannula can be reinserted into the cervical os, should an additional pass be desired. The MVA device can be recharged and attached to the cannula for additional passes into the uterus for aspiration.
- 10. Aspiration should be repeated until there is no tissue noted in the cannula or syringe.
- 11. As the uterus is evacuated, it tends to clamp down, creating a gritty sensation with the cannula. Patients will experience more discomfort at this point.
- 12. If the abortion is not complete based on clinical or ultrasonographic diagnosis, then a medium-sharp uterine curette can be used to curette and feel all quadrants of the uterine cavity. A

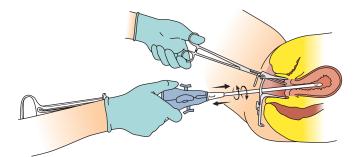

**Figure 127-11** Aspirator is attached to the cannula. Alternatively, the cannula may be attached to the aspirator at the time of initial insertion of the cannula. (Adapted from images of lpas [www.ipas.org].)

**Figure 127-12** Releasing the pinch valve transfers the vacuum through the cannula to the uterus. (From ARHP [Association of Reproductive Health Professionals]: www.arhp.org.)

clean uterus will have a firm, slightly gritty or rough feel. Additional tissue adherent to the uterine walls feels spongy or slippery. Alternatively, a small ring forceps or stone polyp forceps may be used to grasp within the uterine cavity for any additional tissue. Particular caution should be used to avoid perforation when placing metal instruments into the uterus.

- 13. If sharp curettage is used, a final pass with the cannula and MVA device should be done to remove any debris or blood.
- 14. Follow-up transvaginal ultrasonography may be performed immediately after the procedure to demonstrate that the gestational sac and POC have been removed from the uterus.
- The procedure is now completed. Remove the tenaculum and clean the vagina with gauze and check for signs of bleeding or cervical tears.
- 16. Once the vaginal check is complete, the speculum should be removed and the perineum should be wiped down to clear any blood or other fluids that may have collected from the procedure
- 17. Observe the patient for 10 to 15 minutes for bleeding or any unusual reaction. If sedation or general anesthesia was used, follow the appropriate guidelines for postprocedure monitoring.
- 18. The patient is then free to leave, with appropriate follow-up information (see the sample patient education handout, "Instructions after Termination of Pregnancy," online at www. expertconsult.com).
- 19. Examine all tissue using the "float test" to identify POC immediately after the procedure. This step is particularly important in very early abortions, procedures in which scant tissue is obtained, and in patients who are at risk for ectopic pregnancy. The tissue obtained should be washed free of blood with saline or tap water in a strainer. Fragments of tissue can then be suspended in any clear fluid—saline, tap water, and formalin all work—and carefully inspected. Placental tissue has a characteristic "fronding" or finely arborized appearance because of the villi. Backlighting and low-power magnification such with as a colposcope or a magnifying glass is helpful. With a little

**Figure 127-13** Rotating the syringe moves the cannula gently back and forth. Do not withdraw cannula aperture(s) beyond cervical os. Do not grasp syringe by the plunger arms. Blood, tissue, and bubbles will flow through the cannula into the syringe. (Adapted from images of Ipas [www.ipas.org].)

**Figure 127-14** Five-week gestational sac aspirated by manual (*right*) or electric (*left*) vacuum aspiration. Note that the sac appears intact after manual vacuum aspiration. (From ARHP [Association of Reproductive Health Professionals]: www.arhp.org.)

practice, the gestational sac and placental tissue can be distinguished easily from decidua and clot (Fig. 127-14).

20. In some states, the uterine contents must be sent for confirmation of tissue by a pathologist. It is important that clinicians be aware of the laws in their states.

#### **Suction Abortion (Electrical Pump)**

An electrical vacuum pump is the predominant mode of aspiration in many U.S. clinics. Electric power allows for constant flow of suction, which many providers find convenient—particularly for later first-trimester gestations. Rigid disposable plastic cannulas are usually used with machine suction. The *disadvantages* of machine suction are the cost of the machine itself, which may not be affordable in offices that perform uterine aspiration only periodically, as well as the noise, which may not be acceptable in some clinical settings. Performing uterine aspiration with machine suction is similar to using MVA, except that the machine creates suction with an electrical pump.

- 1. Attach the suction machine to the cannula by means of the tubing. Do not activate the suction yet. *The suction is controlled with the slide control on the handle*. It is *not* necessary to turn the machine on and off. Insert the cannula into the uterus.
- Close the valve on the handle to create intrauterine suction. A suction pressure of 55 to 75 mm Hg or greater is required to accomplish the procedure. If suction is inadequate, there is probably a leak in the system that should be identified and corrected.
- 3. Rotate the handle on the tubing as you would with the MVA, and watch the tissue that appears in the curette and tubing.
- 4. After several rotations in each direction, remove the curette while the suction is still on. Reinsert it into the uterus with the suction off. Turn the suction back on, rotate, and remove it again, repeating this until no further tissue is seen in the curette. Even with disposable rigid cannulas, the uterus should feel smaller at the end of the procedure and the operator should feel some sense of "grittiness," although not as great as felt when using MVA.
- Inspect the uterine contents as described in step no. 19 under Manual Vacuum Aspiration.

#### SAMPLE PROCEDURE NOTE

The patient presents to clinic today requesting an elective abortion. She is a G\*\*P\*\* with an LMP of (date) and estimated gestational age (weeks). She is Rh+. The patient was counseled on all of her options and she is sure of her decision. The patient was informed of the risks and benefits of the manual vacuum aspiration procedure and all questions were answered. The patient was informed about the possibility of perforation, infection, bleeding, pain, and missing some tissue. Diazepam (Valium) 10 mg PO and ibuprofen 800 mg PO were given preoperatively. Patient was taken to the procedure room and placed in the dorsal lithotomy position. Bimanual exam revealed an anteverted uterus measuring about 8 weeks' gestation.

Speculum placed without difficulty. Cervix cleansed with Betadine. Approximately 2 mL of 1% lidocaine with epinephrine was placed at the anterior lip. A sharp-tooth tenaculum was placed on the anterior lip. Another 8 mL of lidocaine was placed at the cervicovaginal junction at 4 o'clock and 8 mL placed at 8 o'clock. Cervix was dilated with Dennison dilators to 8 mm. An 8-mm cannula was inserted without difficulty and uterine contents were aspirated without incident. The uterine cavity was explored with forceps and no residual tissue was found. Tenaculum removed. Minimal bleeding at tenaculum site. Patient tolerated procedure well. No complications. Estimated blood loss (EBL) = 30 mL.

Gross inspection of the POC revealed villi and gestational sac consistent with 8-week gestation. POC were then placed in sterile urine cup with formalin and sent to pathology.

Patient recovered in procedure room for 20 minutes after procedure. Vital signs were reassessed and were stable, and patient reported minimal cramping. Patient was released to home at (time) and given printed instruction sheets as well as emergency numbers of the clinic. She was also given an oral contraceptive pill prescription to start this evening. (Alternatively, the Copper T 380A IUD was inserted without difficulty.) Patient agreed with plan and verbalized understanding of instructions. Patient is to follow up for a postoperative visit in 1 to 2 weeks or if experiencing any problems whatsoever.

#### **COMMON ERRORS**

- 1. Poor speculum placement is a common error that can make the procedure more cumbersome than necessary. A speculum placed too anterior to the cervix elongates and narrows the working space needed to perform the procedure. In addition, it can lead to expulsion of the speculum, which can be problematic, particularly if instruments are already on or in the cervix.
- 2. Inadequate traction on the tenaculum placed on the cervix. Tenaculum traction is essential so that the endocervical canal can straighten and decrease the angle between the cervix and the uterine cavity during dilation. This is important to decrease the risk of creating a false passageway or uterine perforation. Some clinicians fear traction will cause the patient to feel pain or cause the tenaculum to rip away from the cervix. It is important that the tenaculum is placed with a large enough "bite" so that there is adequate tissue to hold the tenaculum. A vertical placement of the tenaculum through the cervical os often provides a firm purchase on the cervix when it is short.

#### **COMPLICATIONS**

Less than 0.5% of women experience a complication during a first-trimester surgical abortion, and the risk of death is about one-tenth that during childbirth. However, complications can and do occur, including those resulting in major disability or even death. Careful attention to technique and constant vigilance for complications are mandatory. Complications may occur before the uterine aspiration procedure (misdiagnosis, problems with laminaria, or problems with a paracervical block), during the process of dilation and aspiration (hemorrhage, uterine perforation, inability to evacuate the uterus), or after the patient has returned home (infection, retained POC, hematometra).

#### **Preprocedure Complications**

Misdiagnosis may occur when a woman presenting for a first-trimester abortion procedure has an ectopic pregnancy, a miscarriage, or advanced gestational age. Ectopic pregnancy may be suspected when preprocedure ultrasonography does not show a gestational sac with a yolk sac or fetal pole and the float test of the tissue obtained from such a procedure shows only decidua and not the actual POC. In these cases, additional studies, such as

ultrasonography and serial quantitative  $\beta$ -human chorionic gonadotropin (hCG) determinations, are indicated.

- Miscarriage or early pregnancy failure occurs in about 15% of clinically diagnosed pregnancies. Symptoms include bleeding, cramping, and passage of tissue. Modern means of diagnosing miscarriage in the first trimester include transvaginal ultrasonography and serial quantitative hCG determinations. Patients who are already bleeding may request an abortion and may want to have uterine aspiration even if a nonviable pregnancy is diagnosed or suspected. Alternatively, a woman may elect to initiate expectant management for miscarriage and defer uterine aspiration.
- Advanced gestational age can become a complication if the practitioner initiates a procedure that is beyond his or her training or clinical setting because of inaccurate gestational age dating based on misinterpretation of ultrasonographic or bimanual examination findings. Adnexal masses or uterine fibroids may render bimanual examination less accurate. Fortunately, this will usually result in an overestimation of gestational age rather than underestimation.
- If laminaria have been placed they may fall out, migrate up into the uterus, or fragment. If the laminaria falls out before dilation is effected, mechanical dilation or replacement of the laminaria will be required. Occasionally, the internal os will be stenotic and the laminaria may assume an hourglass configuration, which makes it difficult to remove because the part of the laminaria that is in the intrauterine space is larger than the narrowed, stenotic os. If migration or fragmentation (a piece breaks off and remains intrauterine) is suspected, a careful search of the uterine cavity must be carried out to remove it. Occasionally, a patient will change her mind after the laminaria has been placed. The laminaria can be removed at any time, and in most cases the pregnancy will continue unaffected. However, the patient must be warned of the risk of miscarriage.
- Some patients may experience a vasovagal reaction during laminaria placement or at other times during or after the procedure. Vasovagal reactions involve bradycardia, diaphoresis, nausea, and (rarely) convulsions. Atropine may be administered for treatment and prevention (0.4 mg IV or subcutaneously); the patient's legs should be elevated and her head lowered. If the patient admits to having a low pain threshold or tendency to faint easily, atropine may be given prophylactically 15 to 30 minutes before laminaria placement or the aspiration procedure. Alternatively, atropine may be added to the paracervical block.

#### **Procedural Complications**

- The paracervical block injection can cause some bleeding at the sites
  of injection. Intravascular injection is common despite efforts to
  prevent it. Patients may experience dysphoria, tinnitus, an
  unusual taste in the mouth, and visual disturbances. These sensations are transient. Severe reactions, such as convulsions or allergic reactions, are rare.
- The clinician may be unable to successfully dilate the cervix and enter the uterine cavity. A decision can be made to defer the procedure until after the placement of laminaria or use of misoprostol for cervical ripening.
- Uterine fibroids may prevent or limit access to the uterine cavity. Performing the procedure under ultrasonographic guidance may be the only recourse. Duplication anomalies of the female genital tract result from the failure of the uterus to fuse completely during embryonic development; these anomalies range from arcuate uterus to total duplication of the cervix and uterus in uterus didelphys. The critical point in abortion in a woman with a duplicated system is determining the location of the pregnancy and gaining access to it. Rarely, a pregnancy in a hemiuterine horn is inaccessible to surgical evacuation. Mifepristone medical abortion might be the preferred method in women at less than

- 63 days' estimated gestational age with complex uterine anomalies or fibroids preventing easy access to the uterine cavity.
- Uterine perforation is an uncommon but feared complication that occurs in less than 1 per 1000 procedures. It is generally asymptomatic if caused during the dilation phase. If it occurs with suctioning, then the perforation may be identified by increased pain, hemorrhage, or signs of an acute abdomen. Fat or bowel tissue observed in the suction apparatus is diagnostic, as is passing a blunt instrument up through the perforation. Visualization of the cul de sac by transvaginal or abdominal ultrasonography may point to the possibility of internal bleeding. A culdocentesis is another option to help confirm bleeding (see Chapter 136, Cervical Stenosis and Cervical Dilation). Treatment must be individualized and depends on whether the abortion is complete and whether there is the likelihood of intra-abdominal injury. Minimum treatment includes close observation for 2 to 4 hours or overnight in an inpatient setting. Outpatient observation is reasonable if the perforation did not result in fat or bowel tissue aspiration and there is no abdominal pain or rebound tenderness or evidence of intra-abdominal bleeding. If the risk of hemorrhage or visceral injury is great, laparoscopy or laparotomy may be necessary. If perforation occurs before the uterus is emptied, the procedure may be completed under laparoscopic guidance.
- Hemorrhage occurring during the procedure suggests laceration or perforation or, more commonly, uterine atony with incomplete evacuation of the uterus. Coagulopathy is an uncommon cause of hemorrhage. Lacerations of the cervix can sometimes occur on the ectocervix because of a tenaculum tearing off during the process of cervical dilation. These are usually quite superficial, and bleeding will usually stop with tamponade. Suturing is rarely needed. Puncture sites on the cervix can also bleed briskly and respond to tamponade with the clamping of the ring forceps for a few minutes. Monsel's solution or silver nitrate may be applied to achieve hemostasis if bleeding does not resolve with pressure or packing.
- Atony occurs infrequently but the risk increases when the pregnancy is greater than 10 weeks' gestation. Methylergonovine (Methergine) 0.2 mg intramuscularly or orally may be helpful, and some clinicians use methylergonovine routinely when terminating pregnancies of 8–10 weeks and beyond. Misoprostol may be given in an 800-µg dose by rectal or buccal route for atony. Carboprost tromethamine injection (Hemabate; Pharmacia-Upjohn Pharmaceuticals [Pfizer], NY) given intramuscularly or directly into the cervix is indicated if atony is severe. Retained POC because of incomplete evacuation may be present along with atony. The procedure must be repeated if retained POC are suspected. If bleeding is severe, repeating the procedure may require deeper anesthesia to ensure complete evacuation of all tissue.

#### **Postprocedure Complications**

- Excessive bleeding in the days or weeks after the abortion suggests incomplete abortion, which may be accompanied by infection. Alternatively, a hematometra may have developed in which blood clots gradually fill the uterine cavity and are unable to easily pass through the cervix. Repeating the procedure is the best course for retained POC or hematometra.
- Postabortal infection, or endometritis, is relatively common but not usually severe. Symptoms of endometritis include uterine tenderness, lower abdominal pain, fever, and elevated white blood cell count. Oral antibiotics may be prescribed; however, repeat suction curettage may be required. Rarely, a patient will have severe sepsis or septic shock and require aggressive treatment, including hospital admission, broad-spectrum IV antibiotics (e.g., gentamicin and clindamycin), fluids, and even hysterectomy.
- Late sequelae, such as infertility, premature labor, and incompetent cervix, have been studied extensively and are not thought to be associated with first-trimester aspiration procedures using modern

methods. Asherman's syndrome is the formation of intrauterine or cervical adhesions after curettage. Because uterine aspiration has replaced curettage as the primary technique of first-trimester abortion Asherman's syndrome is a very uncommon complication and usually involves cervical rather than intrauterine adhesions. The cervical adhesions can be treated by using small dilators to reopen the endocervical canal.

#### POSTPROCEDURE MANAGEMENT

Doxycycline 100 mg orally twice a day for 3 days is recommended as routine surgical prophylaxis, with the first dose given before or soon after the procedure. Methylergonovine 0.2 mg administered orally every 6 hours for six doses is occasionally given to assist in contracting the uterus and preventing bleeding in women having aspiration abortion after 10–12 weeks gestational age or experiencing post-procedure bleeding because of uterine atony. If the provider is concerned that the patient may have more bleeding than usual, misoprostol can be given, although the U.S. Food and Drug Administration has not approved its use in this manner. Effective contraception should be offered to the patient and prescribed or provided the same day the abortion is performed. Intrauterine devices may be placed immediately after the conclusion of a first-trimester uterine aspiration abortion. Hormonal contraceptives may be started the same day of an abortion procedure.

#### POSTPROCEDURE PATIENT EDUCATION

No sexual activity is advisable for 1 week. Also see the sample patient education form available online at www.expertconsult.com.

#### INTERPRETATION OF RESULTS

The POC must be examined after the procedure either by the float test or by sending them to a laboratory for pathology. In states that do not require pathologic examination, many operators will defer sending POC for pathologic analysis. If scant tissue is noted or a molar pregnancy is suspected based on ultrasonographic findings or gross review of the POC, evaluation by a pathologist should be considered. If the pathology is read as consistent with a molar or partial molar pregnancy, then appropriate follow-up with a clinician skilled in the management of gestational trophoblastic disease is essential. In addition, a pathology report that notes trophoblastic tissue inconsistent with preprocedural gestational age assessment requires follow-up. The patient should be contacted and reassessed with a repeat bimanual examination, ultrasonography, or serial quantitative hCG determinations, as indicated.

## Pregnancy Termination: Medication Abortion

Ruth Lesnewski • Linda Prine

Medication abortion is the elective termination of a pregnancy using pharmaceuticals. Since 2000, when mifepristone became available in the United States, mifepristone/misoprostol has been the most commonly used medication abortion regimen in this country. Alternate regimens use methotrexate/misoprostol or misoprostol only. Medications can be used to end an unintended pregnancy of up to 7 to 9 weeks' gestational age, depending on the regimen available. Medication abortion has proven to be remarkably safe and effective, and it provides women with an alternative to surgical abortion.

## SELECTING MEDICATION OR SURGICAL ABORTION

Women with unintended pregnancy often present to their primary care provider for pregnancy diagnosis and counseling, treatment, or referral. Physicians who do not offer abortion in their office can counsel women about the factors influencing selection of medication or aspiration abortion methods. Table 128-1 provides an overview of both methods. Although aspiration abortion is quicker and slightly more effective, medication abortion offers women more privacy, less instrumentation, and a feeling of control over the experience (see Chapter 127, Pregnancy Termination: First-Trimester Suction Aspiration). Because medication regimens involve cramping and bleeding at home, women who choose medication abortion should have a safe, supportive environment available to them. Women who select medication abortion must agree to return for a follow-up visit and to have an aspiration procedure if the medications fail.

#### **INDICATION**

Elective termination of pregnancy (up to 63 days' gestation with some regimens) is the indication for medication abortion.

#### **CONTRAINDICATIONS**

#### **Absolute**

- Ectopic pregnancy (mifepristone/misoprostol protocols)
- Uncertain gestational age (must establish gestational age before procedure)

#### **Relative**

- Adrenal failure
- Severe asthma
- Long-term systemic glucocorticoid therapy
- Intrauterine contraceptive device in place (must be removed before procedure)

- Anticoagulation
- Severe anemia

#### **EQUIPMENT AND SUPPLIES**

Physicians must order mifepristone directly from its manufacturer and have a prescriber's agreement in place with the manufacturer (available at www.earlyoptionpill.com). This medication cannot be obtained from pharmacies. If possible, physicians should order misoprostol as well and dispense it directly to patients; otherwise, patients may have difficulty obtaining misoprostol as quickly as needed. Routine ultrasonography is not required. However, clinicians need access to ultrasonography (either in-office or by referral) for women with an uncertain last menstrual period, size/dates discrepancy, or increased risk of ectopic pregnancy.

#### PREPROCEDURE PATIENT EDUCATION

Patients who undergo mifepristone/misoprostol abortion must read the Medication Guide (see Guide online at www.earlyoptionpill.com/userfiles/file/Med%20Guide%204-22-09%20Final.pdf) produced by Danco Laboratories (New York), mifepristone's sole

FDA, U.S. Food and Drug Administration

U.S. manufacturer (see Online Resources). Patients must then sign Danco's Patient Agreement (Fig. 128-1). Clinicians must also provide patients with an office-specific consent form (Fig. 128-2; see also at www.expertconsult.com), which describes the risks, benefits, and possible complications as well as the correct dosing and administration of both medications. After obtaining informed consent, clinicians should have women sign the consent form. Clinicians should also review the misoprostol aftercare instructions (Figs. 128-3 and 128-4) with their patients carefully to ensure that they understand guidelines for administering misoprostol at home, and to ensure that the practitioner's contact information is clear.

#### **PROCEDURE**

#### Mifepristone and Misoprostol

Mifepristone is a progestin blocker that causes decidual necrosis. Misoprostol is a prostaglandin analog that causes uterine contraction and expulsion of pregnancy. Mifepristone/misoprostol abortion involves several steps and at least two office visits. The physician determines, by history, ultrasonography, or bimanual sizing with a quantitative human chorionic gonadotropin (hCG) level, that the pregnancy is less than 7 to 9 weeks (depending on regimen). After pregnancy dating confirmation, options counseling, selection of method, and completion of necessary paperwork, the patient takes mifepristone orally in the physician's office. Six to 72 hours later (depending on the protocol in use), she takes misoprostol at home. Misoprostol can be used orally, vaginally, or buccally. The dosing and timing of administration vary according to route; see Table 128-2 for details. Soon after she takes misoprostol, the patient experiences cramping and bleeding. At first, cramps can be quite intense, often requiring a combination of nonsteroidal anti-inflammatory drug and a mild narcotic. The bleeding that follows may be heavy, with large clots. The patient should call her clinician if she bleeds enough to soak through more than two pads per hour for 2 consecutive hours. Cramps and bleeding decrease in intensity after the first few hours but can persist in a milder form for 3 weeks or more. Bleeding sometimes lasts long enough to blend into the woman's next menses.

Rh-negative women should receive Rh immune globulin. A 50-µg dose (MICRhoGAM) should be given before using misoprostol or within 72 hours of bleeding. Patients should be informed that this medication is a human blood derivative. Patients who refuse the injection should sign a statement documenting their decision.

Four to 14 days after the initial visit, the patient returns for follow-up. At this visit, the physician confirms the procedure's success by history and by either repeating the ultrasonographic examination or repeating the quantitative hCG (depending on which was done at the initial visit). The physician also revisits the woman's choice of an ongoing contraceptive method. If the quantitative hCG is repeated, it will drop by 75% from the previous week, indicating the success of the medication abortion.

The U.S. Food and Drug Administration (FDA) approved mifepristone in 2000, using evidence from studies completed in 1996 and earlier. After 1996, further research on medication abortion led to simpler, more convenient protocols with higher efficacy and lower cost. Table 128-2 compares the FDA protocol with two updated protocols. Most clinicians in the United States use an updated protocol for mifepristone/misoprostol abortion.

## Methotrexate and Misoprostol and Misoprostol-Only Regimens

Of the three most commonly used medication abortion regimens, mifepristone/misoprostol has the highest efficacy and best side effect

profile. Methotrexate/misoprostol, used in the United States before mifepristone's release, works over weeks rather than days, requires multiple office visits, and can be used in pregnancies of less than 8 weeks' gestation. Methotrexate has the advantage of treating early ectopic pregnancy, whereas mifepristone and misoprostol regimens do *not* end ectopic pregnancies. Misoprostol-only regimens require several doses, each with significant side effects. This regimen has widespread lay use in countries where abortion remains legally restricted or is too expensive.

#### **SAMPLE PROCEDURE NOTES**

See Initial Visit Note and Follow-up Visit Note (Figs. 128-5 and 128-6) for examples of documentation for the mifepristone/misoprostol regimen.

#### **COMPLICATIONS**

Mifepristone causes far fewer side effects than does misoprostol. Misoprostol's side effects include nausea, vomiting, fever, chills, and uterine cramping. Vaginal or buccal administration causes fewer side effects than oral administration. Misoprostol is believed to be a teratogen when administered in early pregnancy if abortion should fail to occur.

Although all are uncommon, the major complications of mife-pristone/misoprostol abortion are continuation of the pregnancy, retained products of conception, heavy bleeding, and infection. Continuation of pregnancy may occur slightly more often with later gestational age. Overall, the rate of continuing pregnancy is under 1%. Incomplete abortion—that is, failure to expel all pregnancy tissue with medications alone—occurs in 0.6% to 3% of women. The rate depends in part on clinicians' and patients' threshold for resorting to an aspiration procedure. Cramping and bleeding are expected with medication abortion, but bleeding heavy enough to require emergency care (or heavy enough to require transfusion) occurs in fewer than 0.1% of patients. The treatment for continuing pregnancy, retained products of conception, and heavy bleeding is the same: a uterine aspiration procedure.

Endometritis after medication abortion is extremely rare. The rate varies from 0.09% to 0.5%, and treatment requires broadspectrum antibiotics. Over the past few years, five North American women have died because of toxic shock after mifepristone/misoprostol abortion. Four of these deaths were associated with a specific pathogen, Clostridium sordellii. Although the death rate associated with medication abortion remains exceedingly low—under 1 in 100,000—and very little is known about the risk factors for C. sordelli infection, many clinicians began to advise buccal rather than vaginal administration of misoprostol after these deaths.

## POSTPROCEDURE MANAGEMENT AND EDUCATION

The mifepristone aftercare instruction sheets explain misoprostol administration, use of pain medications, and initiation of contraception (see Figs. 128-3 and 128-4).

#### **PATIENT EDUCATION GUIDES**

See the Medication Guide for Mifeprex at www.earlyoptionpill.com/userfiles/file/Med%20Guide%204-22-09%20Final.pdf.

See the consent form online at www.expertconsult.com. See Figures 128-1 through 128-4 for patient information.

#### PATIENT AGREEMENT Mifeprex (mifepristone) Tablets

- 1. I have read the attached MEDICATION GUIDE for using Mifeprex\* and misoprostol to end my pregnancy.
- 2. I discussed the information with my health care provider.
- 3. My provider answered all my questions and told me about the risks and benefits of using Mifeprex and misoprostol to end my pregnancy.
- 4. I believe I am no more than 49 days (7 weeks) pregnant.
- 5. I understand that I will take Mifeprex in my provider's office (Day 1).
- 6. I understand that I will take misoprostol in my provider's office two days after I take Mifeprex (Day 3).
- 7. My provider gave me advice on what to do if I develop heavy bleeding or need emergency care due to the treatment.
- 8. Bleeding and cramping do not mean that my pregnancy has ended. Therefore, I must return to my provider's office in about 2 weeks (about Day 14) after I take Mifeprex to be sure that my pregnancy has ended and that I am well.
- 9. I know that, in some cases, the treatment will not work. This happens in about 5 to 8 women out of 100 who use this treatment.
- 10. I understand that if my pregnancy continues after any part of the treatment, there is a chance that there may be birth defects. If my pregnancy continues after treatment with Mifeprex and misoprostol, I will talk with my provider about my choices, which may include a surgical procedure to end my pregnancy.
- 11. I understand that if the medicines I take do not end my pregnancy and I decide to have a surgical procedure to end my pregnancy, or if I need a surgical procedure to stop bleeding, my provider will do the procedure or refer me to another provider who will. I have that provider's name, address and phone number.
- 12. I have my provider's name, address and phone number and know that I can call if I have any questions or concerns.
- 13. I have decided to take Mifeprex and misoprostol to end my pregnancy and will follow my provider's advice about when to take each drug and what to do in an emergency.
- 14. I will do the following:
  - Contact my provider right away if in the days after treatment I have a fever of 100.4°F or higher that lasts for more than 4 hours or severe abdominal pain.
  - Contact my provider right away if I have heavy bleeding (soaking through two thick full-size sanitary pads per hour for two consecutive hours).
  - Contact my provider right away if I have abdominal pain or discomfort, or I am "feeling sick," including weakness, nausea, vomiting or diarrhea, more than 24 hours after taking misoprostol.
  - Take the MEDICATION GUIDE with me when I visit an emergency room or a provider who did not give me Mifeprex, so that they will understand that I am having a medical abortion with Mifeprex.
  - Return to my provider's office in 2 days (Day 3) to check if my pregnancy has ended. My provider will give me misoprostol if I am still pregnant.
  - Return to my provider's office about 14 days after beginning treatment to be sure that my pregnancy has ended and that I am well.

Patient Signature: Patient Name (print): Date:
The patient signed the PATIENT AGREEMENT in my presence after I counseled her and answered all her questions. I have given her the MEDICATION GUIDE for mifepristone.
Provider's Signature: Name of Provider (print): Date:
After the patient and the provider sign this PATIENT AGREEMENT, give 1 copy to the patient before she leaves the office and put 1 copy in her medical record. Give a copy of the MEDICATION GUIDE to the patient. Rev 2: 7/19/05
*Mifeprex is a registered trademark of Danco Laboratories, LLC.

Write your initials before each statement to show that you understand and agree with it.    Understand that this consent form differs from the Mifeprex patient agreement.	Consent for Mifepristone/Misoprostol Abortion
I understand that my three choices for this pregnancy are parenthood, adoption and abortion.  "Medication abortion" means an abortion using drugs. A suction abortion uses instruments to empty the uterus or womb. I know that I should not begin a medication abortion unless I am sure that I want to end my pregnancy. I am willing to have a suction abortion must be done within the first 9 weeks of pregnancy. A physical exam, a blood test and/or an ultrasound exam will be done to confirm the size of my pregnancy.  I will take 2 medications. The first is mifepristone, which blocks a hormone needed to continue a pregnancy. I will take a 200 mg dose because research shows this dose is effective. The second drug is misoprostol. It causes the cramps which expel the pregnancy.  Before I take these medications, I may have blood tests to check for anemia and to check my Rh type. If I am Rh negative, I will get a shot of MiCRhoGAM.  I will swallow the mifepristone tablet before I leave the health center. I know that this can cause some nausea and diarrhea, and later cramps.  I know that I will take 4 misoprostol tablets home with me.  BUCCAL MISOPROSTOL: I will put 2 misoprostol tablets in each cheek no sooner than 24 hours after I swallow the mifepristone, but before 72 hours have passed.  I will receive prescriptions for pain medications.  I understand that 1 to 6 hours after I insert the misoprostol, I will have cramping and bleeding. The cramping can be very strong for a few hours, but usually not for more than 24 hours. The bleeding can be quite heavy with clots for a few hours. I may see some pregnancy tissue (usually white or gray in color).  If the heavy bleeding lasts for more than 12 hours, or if I soak more than two maxi pads each hour for two hours in a row, I should call my provider. I know that I should also call if I do NOT bleed within 24 hours of inserting the misoprostol.  If I start to feel very ill, I will call the health center. Very rarely, women have had "toxic shock" type illness after a medication abo	Write your initials before each statement to show that you understand and agree with it.

BUCCAL MISOPROSTOL: I will put 2 misoprostol tablets in each cheek no sooner than 24 hours after I swallow the mifepristone, but before 48 hours have passed.  I will receive prescriptions for pain medications.  I understand that 1 to 6 hours after I insert the misoprostol, I will have cramping and bleeding. The cramping can be very strong for a few hours, but usually not for more than 24 hours. The bleeding can be quite heavy with clots for a few hours. I may see some pregnancy tissue (usually white or gray in color).  If the heavy bleeding lasts for more than 12 hours, or if I soak more than two maxi pads each hour for two hours in a row, I should call my provider. I know that I should also call if I do NOT bleed within 24 hours of inserting the misoprostol.  If I start to feel very ill, I will call the health center. Very rarely, women have had "toxic shock" type illness after a medication abortion.  I know that I should return for my one-week check-up to be sure that the abortion is complete. At this visit, an ultrasound o	I understand that my three choices for this pregnancy are parenthood, adoption and abortion.
test and/or an ultrasound exam will be done to confirm the size of my pregnancy.  I will take 2 medications. The first is mifepristone, which blocks a hormone needed to continue a pregnancy. I will take a 200 mg dose because research shows this dose is effective. The second drug is misoprostol. It causes the cramps which expel the pregnancy.  Before I take these medications, I may have blood tests to check for anemia and to check my Rh type. If I am Rh negative, I will get a shot of MICRhoGAM.  I will swallow the mifepristone tablet before I leave the health center. I know that this can cause some nausea and diarrhea, and later cramps.  I know that I will take 4 misoprostol tablets home with me.  BUCCAL MISOPROSTOL: I will put 2 misoprostol tablets in each cheek no sooner than 24 hours after I swallow the mifepristone, but before 48 hours have passed.  Or  VAGINAL MISOPROSTOL: I will put 4 misoprostol tablets in my vagina no sooner than 6 hours after I swallow the mifepristone, but before 72 hours have passed.  I will receive prescriptions for pain medications.  I understand that 1 to 6 hours after I insert the misoprostol, I will have cramping and bleeding. The cramping can be very strong for a few hours, but usually not for more than 24 hours. The bleeding can be quite heavy with clots for a few hours. I may see some pregnancy tissue (usually white or gray in color).  If the heavy bleeding lasts for more than 12 hours, or if I soak more than two maxi pads each hour for two hours in a row, I should call my provider. Medication Abortion (Vaginal Misoprostol) Patient Aftercare Sheet
Today,, you took mifepristone to end your pregnancy. You took 200 milligrams of mifepristone atam/pm. You may have some vaginal bleeding after taking this pill.
Any time from 6 to 72 hours from now,am/pm, you must take another medicine, misoprostol (also called Cytotec). Choose a time when you have had a good meal and plenty of rest. Swallow one ibuprofen pill one hour before you take the misoprostol—this will help decrease your cramps. You must take the misoprostol even if you have started to bleed.
Each misoprostol pill is 200 micrograms. <b>Place 4 misoprostol pills in your vagina.</b> Lie down for 30 minutes. It's OK if the pills fall out after 30 minutes.
What to expect Misoprostol causes cramping and bleeding, often with clots. The cramps and bleeding may be much more than you get with a period. The cramps usually start 2 to 4 hours after you insert the pills, and may last for 3 to 5 hours. This heavy bleeding means that the treatment is working. The bleeding often lasts 1 to 2 weeks, and it may stop and start a few times.
You may have a lot of pain or cramps—if so, take pain medicine. You can take ibuprofen (Motrin or Advil) up to 800 milligrams every 8 hours and/or hydrocodone up to 2 pills every 4–6 hours. You can also use a heating pad to relieve the pain. Some women get nausea, diarrhea or chills. This should get better in a few hours.
You <b>should</b> call me if  • Your bleeding soaks through more than 2 maxi pads per hour for 2 hours.  • You do <b>not</b> bleed within 24 hours after inserting the misoprostol.  • You start to feel very ill after the heavy cramping and bleeding are over.
To reach me  Call my 24-hour number: If you have any questions or think something is going wrong, call this number and I will call you back. It may take me 10 to 15 minutes to return your call. No question is too small. Please feel free to call me.
Follow-up You have an appointment to come back to my office onat am/pm. At this visit I will make sure that the abortion is complete.
Birth control If you want to use birth control pills, patch, or ring, I have given you a prescription. You should start these on, even if you are still bleeding.

Medication Abortion Initial Visit Note			
Subjective:			
is here with an unintended pregnancy. We fully discussed all of her options. The patient has indicated that this is not a good time for her to become a parent and would like to end the pregnancy. The options, including medication abortion, suction abortion with local anesthesia, and referral for suction abortion under general anesthesia, were discussed. She has chosen a medication abortion with mifepristone and misoprostol.			
Past Medical History:			
Past Surgical History:			
GP			
Her obstetric and gynecologic history is Her prior methods of contraception:			
She IS IS NOT in a safe situation at home and IDOES IDOES NOT describe a situation that might be high risk for abuse.			
The patient  DOES  DOES NOT meet the following criteria: There is no IUD in place, she is not allergic to prostaglandins/mifepristone, there is no chronic adrenal failure, no long-term systemic corticosteroid use, no concurrent anticoagulant therapy, and no hemorrhagic disorders.			
Rh status:			
Physical examination Vital signs:			
General appearance:			
Uterus: weeks size			
ULTRASOUND (limited study for the purpose of determining gestational age):  Performed:			
Assessment			
is a good candidate for medical abortion with a pregnancy at less than 63 days gestational age. She has no medical contraindications. She understands the protocol and possible side effects, the need for a follow-up visit, and the need for a suction procedure if the medical abortion fails. She knows how to contact me in case of an emergency.			
Mifeprex medication guide given:  Mifeprex provider / patient agreement signed:  Updated consent form signed:  Pain medication prescribed as per orders.  Mifeprex lot number recorded: by nursing, see nursing note.  Dispensed 4 tablets of misoprostol (200 mcg each) for home use.  Patient information sheet given; this sheet details the self-insertion of the misoprostol and the expected bleeding patterns.  RhoGAM given:  YES  NO  Not applicable  The certificate of induced termination was sent to the health department  YES  NO  Not applicable  The sonogram (if done) is to be scanned into the record along with the Mifeprex and alternative consent form.  She has chosen  as her ongoing contraceptive method and has been instructed on when to begin this method. (OCP users to start one or two days after the insertion of the misoprostol)			
Follow-up visit scheduled in approximately 1–2 weeks			

Medication Abortion Follow-up Visit Note
presents for follow-up after medical abortion.  Within 24 hours after taking misoprostol, she had cramping and bleeding.  Bleeding now reported as:  She has no symptoms of pregnancy.
Objective Vital signs: General appearance: Ultrasound (if done) shows absence of gestational sac and thickening of the endometrial lining:  YES NO Not applicable
Assessment Abortion completion assessed by: History:
Plan Contraception plan reviewed: ☐ YES ☐ NO Repeat hCG level ordered: ☐ YES ☐ NO ☐ Not applicable Discussed duration of bleeding and potential complications. No restrictions on activity.

Figure 128-6 Procedure note for subsequent visit.

#### **BILLING AND CODING**

The following codes can be used to bill for medication abortion.

#### Visit I

J8499

The first visit includes verification of pregnancy and pregnancy date, counseling, and administration of mifepristone:

CPT 99204 or 99214 Level 4 new or established patient E/M visit ICD-9 635.92 Legally induced abortion, without mention of complication, complete

Prescription drug, oral, nonchemo, not

otherwise specified

or

J3490 Unclassified drug

If J codes are not accepted by insurance carrier, use 99070 (a cost-of-materials CPT code) or S0190 for mifepristone. Each insurance carrier may reimburse for mifepristone using a different code. The name of the drug (mifepristone), the dosage (200 mg), and the 11-digit national drug code (NDC) from the drug package must accompany this claim. In addition, submit a copy of the drug invoice to show the cost of the drug.

76815 Limited ultrasound, pregnant uterus

or

76817 Transvaginal ultrasound, pregnant uterus

In addition, submit codes for appropriate laboratory tests or MICRhoGAM (90385) if done in office.

#### Visit 2

The second visit is to verify that the pregnancy has ended.

CPT 99213 or 99214 Level 3 or 4 E/M visit for established patient CPT 76817 or 76815 Ultrasound

ICD-9 635.92 Legally induced abortion, without mention of complication, complete

## **EMERGENCY CONTRACEPTION**

Steven H. Eisinger • Eric A. Smith

Emergency contraception (EC) is treatment intended for women who have had unprotected intercourse and wish to avoid pregnancy. Ingestion of high doses of sex steroids administered within 120 hours of exposure is known to prevent pregnancy. The mechanism remains unclear but appears to involve either inhibition or delay of ovulation or interference with implantation of a fertilized ovum. Some regard this as a form of abortion, but others believe that abortion occurs only after implantation. If taken by an already pregnant patient, current commercially available medical EC does not interrupt the pregnancy and there is no proven harm to the developing fetus. Studies in China have shown that mifepristone used as a form of EC is equally or more efficacious, but this use is not approved and could potentially harm an established pregnancy. Other selective progesterone receptor modulator drugs, such as ulipristal, are under active investigation.

Lack of knowledge and access to EC appear to be the major barriers to the provision of EC. Both doctors and patients are often unaware of EC. Critical delays in treatment may occur when doctors require an office visit before prescribing or the patient has to search for a pharmacy that carries the prescription. For these reasons, the American College of Obstetricians and Gynecologists has advocated the practice of discussing EC with all patients who are sexually active and at risk for a contraceptive failure. In the primary care setting, this should include both female and male patients of reproductive age. Telephone prescribing appears to be safe.

The cost of EC varies from \$21 to \$50 retail. Availability has been sporadic in the past. Indeed, the safety profile of the progestinonly method resulted in the U.S. Food and Drug Administration (FDA) approving Plan B (Duramed Pharmaceuticals, Cincinnati, Ohio) for nonprescription sale to adults in August of 2006. In April of 2009, the FDA decreased the minimum age of over-the-counter (OTC) purchase of EC to 17 years old. However, the medication remains behind the pharmacy counter and requires a prescription for patients younger than 17 years of age. Access may still be limited by pharmacists' unwillingness to dispense the medication and the lack of privacy when requesting EC from a pharmacist.

#### **INDICATIONS**

Women who have had intercourse within 5 days and who have used no contraception during intercourse, whose method of contraception failed (e.g., a broken condom), or who have been victims of sexual assault are candidates for EC if they are at risk for pregnancy. Women at midmenstrual cycle who may be near ovulation are at greatest risk, but risk exists at any time in the cycle and EC need not be "timed" to coincide with an individual's menstrual cycle. See Figure 129-1 for an approach to EC use.

#### **CONTRAINDICATIONS**

The progestin-only method (Plan B One Step, Next Choice, or their equivalent) has no known medical contraindications. The World

Health Organization has stated that the only contraindication to EC is an ongoing pregnancy. No teratogenic effects have been identified, however. Medical contraindications to oral contraceptives, such as severe hypertension and history of thromboembolism, should be considered but have not been shown to be significant with the short dosage schedule.

#### **PRECAUTIONS**

An accurate timeline of exposure is critical to the use of EC. A pregnancy test can be considered before administration. Testing for and treatment of sexually transmitted infections should be offered and encouraged. An adequate plan for contraception after EC use should be recommended.

#### PREPROCEDURE PATIENT EDUCATION

Because the product is available OTC, preprocedure counseling may not be possible. If the patient contacts her physician before taking EC, she should be informed of the risks and benefits of the medication as outlined in this chapter and the patient education handout. Educating patients about the availability of EC at health maintenance visits may be appropriate.

#### **PROCEDURE**

#### Medical

Plan B One Step (Duramed Pharmaceuticals, Cincinnati, OH) and Next Choice (Watson Pharma, Morristown, NJ) are commercial oral EC regimens available by prescription (for those <17 years of age) and OTC (for those >17 years of age). Plan B One Step consists of a single tablet containing 1.5 mg of levonorgestrel. Plan B (being phased out) and Next Choice consist of two tablets, each containing 0.75 mg of levonorgestrel. Following the FDA-approved regimens, the first or single pill is taken as soon as possible within 72 hours after exposure and, if part of the prescription, the second pill is taken 12 hours later. An alternate and equally effective regimen to the two-pill prescription is to take both tablets (1.5 mg levonorgestrel) as a single dose. Further research has also demonstrated effectiveness of the method up to 120 hours (5 days) after exposure, with declining success as delay increases.

A dual-hormone brand of EC known as Preven is no longer available by prescription, but hormones found in certain common oral contraceptives, including a number of generic preparations, can be used to replicate it. It may be advantageous to know how to provide the *dual-hormone* ("Yuzpe") method because it may be more readily available and less expensive than commercially available EC if the patient has access to oral contraceptive pills. Two widely used forms of progestin can be used: levonorgestrel (like Plan B, Plan B One Step, and Next Choice) and norgestrel. Twice as much norgestrel is required for the same therapeutic effect (0.75 mg levonorgestrel or 1.50 mg norgestrel per dose). Determining the

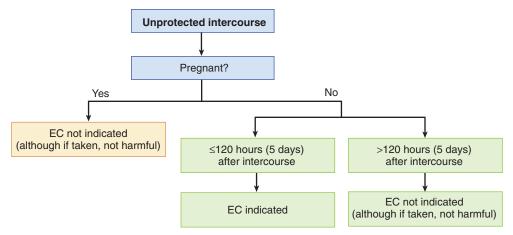

Figure 129-1 Emergency contraception (EC) decision pathway.

correct number and color of active pills available to the patient may require help from the local pharmacy (Table 129-1).

The prescribing regimen is similar for all the options: the first dose is taken immediately, and, when indicated, the second dose is taken 12 hours later. Only Plan B has been proven to be equally effective if both of the tablets are taken as a single dose, and thus received FDA approval for Plan B One Step. Evidence shows that early administration enhances efficacy. The greatest efficacy occurs when the regimen starts within 24 hours of exposure, but the treatment may be initiated up to 120 hours after exposure.

In a head-to-head randomized, blinded study the progestin-only method had an efficacy up to 85%, whereas the dual-hormone method had an efficacy up to 57%. Thus, progestin-only EC is the better option when available.

Female patients may be given a prescription to be held in reserve in case of an exposure. A *national telephone hotline* (not associated with the manufacturers) has been established to provide the names and numbers of local clinics that provide emergency contraceptive services: 888-NOT-2-LATE (888-668-2528).

#### **Intrauterine Contraceptive Device**

Another approach to EC is the placement of a copper intrauterine device (IUD), ParaGard. The IUD is effective up to 1 week after exposure and is significantly more effective than oral methods, with a reduced risk of pregnancy of 99% if inserted within 5 days of unprotected intercourse. IUD insertion has its own risks and disadvantages, but placement for EC has the advantage of immediate and continuous contraception. See Chapter 145, Intrauterine Device Insertion, for a full discussion of IUD insertion.

#### **COMPLICATIONS**

With the *dual-hormone* method, *nausea* and *vomiting* are common problems. Therefore, a prophylactic antiemetic is recommended before the hormones are administered. *Breast tenderness* may also occur. Side effects are less frequent with the progestin-only methods. *Menses may be early, on time, or delayed* after treatment. If the menstrual delay is 21 days or more from the date of treatment, a pregnancy test should be performed. If the medication is vomited within the first hour of ingestion, repeat administration with an antiemetic is indicated. If vomited more than 1 hour post-ingestion, repeat administration is still advised.

#### POSTPROCEDURE MANAGEMENT

Discuss a post-EC plan for contraception and ensure that the patient understands that EC is not an effective method of continuous

## BARRIER CONTRACEPTIVES: CERVICAL CAPS, CONDOMS, AND DIAPHRAGMS

Beth A. Choby

Cervical barriers are relatively safe and inexpensive options for contraception. They are immediately effective and reversible and have few side effects. Barrier methods are options for women who have contraindications to hormonal contraceptives, cannot tolerate intrauterine devices, or are not ready for sterilization. Additional benefits include ease of transportability, safety during lactation, and the convenience of flexible timing of insertion. Current barrier methods are 80% effective in preventing pregnancy when used correctly and consistently. Table 130-1 lists various barrier options, contraceptive failure rates, and costs.

Although more options for barrier contraception are available today than ever before, the percentage of women choosing barrier methods is small. Only 0.3% of women used a diaphragm for contraception in 2002; in the 1980s, 8.1% of women selected this method. A possible protective effect against sexually transmitted infection (STI) has focused renewed attention on barrier contraception. Protection is thought to occur through mechanical blocking of exposure to semen and bodily fluids. Most barrier devices are used in combination with nonoxynol-9, but spermicide itself does not enhance protection against STIs. The Centers for Disease Control and Prevention recommends that women at high risk for human immunodeficiency virus (HIV) infection avoid nonoxynol-9 spermicides because they offer no protection against STIs and may increase the risk of HIV infection.

#### **CERVICAL CAPS**

Cervical caps are small, firm silicone cups that adhere to the cervix by suction. Four types of cervical cap are available internationally. The Prentif cap was approved by the U.S. Food and Drug Administration (FDA) in May 1988, but was voluntarily removed from the U.S. market by the manufacturer in March 2005. The only cervical cap currently available in the United States is the FemCap (Fig. 130-1). The FemCap is silicone based and shaped like a sailor's hat. Initial efficacy studies of the FemCap were based on the firstgeneration product, which is no longer available. A Cochrane Database Review comparing the first-generation FemCap with the diaphragm found that the FemCap was less effective in preventing pregnancy. Fourteen percent of nulliparous women using the FemCap became pregnant during the first year with typical use; parous women had a 29% failure rate. The first-generation FemCap is now considered obsolete and has been replaced with a secondgeneration design. Although research on the effectiveness of the second-generation FemCap is limited, the typical failure rate is estimated to be 7.6%. Failure rates with perfect use are 2% to 4%. Dislodgement of the first-generation device occurred in one third

of users; the second-generation FemCap dislodgement rate is estimated at 2%. Future studies should better clarify long-term efficacy. The cap has a high level of patient acceptability, and FemCap users may have decreased risk of urinary tract infections compared with women using a diaphragm. The Prentif cap was associated with cervical dysplasia when the device was used for longer than 3 months. Although small trials do not link cytologic abnormalities with FemCap use, baseline Papanicolaou screening (Pap smear) and annual surveillance are reasonable in women choosing this method.

#### **Anatomy**

The FemCap has a dome that fits over the cervix. An asymmetric brim flares outward to fit against the vaginal fornices (see Fig. 130.1)

#### Indications

- Prevention of pregnancy
- Possible protection against STIs

#### **Contraindications**

#### **Absolute**

- Allergy to silicone
- Less than 10 weeks postpartum
- History of toxic shock syndrome
- History of recent cervical surgery or abortion
- Cancer of the vulva, vagina, cervix, or uterus
- Anatomic abnormalities of the vagina, uterus, or cervix

#### Relative

- Uterine prolapse
- Patient unable to be properly fitted
- Patient unable to understand instructions for use or proper insertion/removal of the device
- Current genital tract infection
- Poor vaginal muscle tone
- Vaginal or cervical tissue breakdown

#### **Equipment and Supplies**

The FemCap is a clear silicone device that covers both the cervix and vaginal fornices. A strap over the dome augments removal.

<b>TABLE 130-1</b>	Comparison of Female Barrier Contraceptives						
Method	Over- the- Counter	Multiuse/ Reusable	l Year Failure Rate with Typical Use (%)	Timing of Insertion (Maximum Hours Prior to Intercourse)	Time to Be Left in after Intercourse (Hours)	Maximum Duration of Use (Hours)	Cost (US\$)
Diaphragm FemCap	No No	Yes Yes	16 7.6 <sup>†</sup>	6 40	6	24 48	50* 65: includes video/DVD, device and instructions*
FC2 female condom	Yes	No	21	8	Remove after intercourse	One time use	2.50
Lea's shield	No	Yes	15	Prior to intercourse	8	48	65; direct order from internet*
Sponge	Yes	No	13–17	24	6	30	7.50–9 for pack of 3
Male condom	Yes	No	85	Prior to intercourse	Remove after ejaculation		0.50

<sup>\*</sup>Does not include costs for spermicide.

Spermicide is applied in the groove between the brim and the dome. The cap is available in three sizes. Determining the correct size depends in general on the user's childbearing history:

- 22 mm (Small): use in nulliparous women
- 26 mm (Medium): use in women with a previous abortion or cesarean delivery
- 30 mm (Large): use in women with history of vaginal delivery

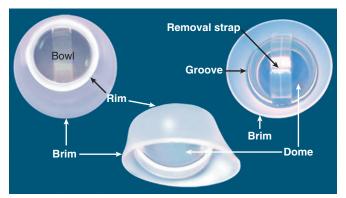

The FemCap kit contains the device, physician instructions for fitting, and a patient education DVD/video detailing product use. Cost of the kit averages \$65.

#### **Precautions**

- Perform a pelvic examination before a cervical cap fitting. A Pap smear is recommended at baseline and then annually. Cervical cultures should be obtained in women at risk for STIs.
- Cervical cap fitting is contraindicated during pregnancy or the postpartum period (10 weeks).

## Patient Education: Cervical Cap Use for Contraception

- Before use, one third of the inner side of the dome should be filled with spermicidal jelly.
- The jelly should not be applied to the inner surface of the rim.
- The cap may be inserted at any time from immediately before intercourse up to 40 hours before intercourse. It is most easily inserted in a squatting or semireclining position.
- The cap should be left in place for at least 6 hours following intercourse.

**Figure 130-1** The FemCap cervical cap. (Courtesy of FemCap, Inc., Del Mar, Calif; with permission.)

- The cap may be left in place for up to 48 hours.
- If intercourse occurs more than once while the cap is in place, no additional spermicide is needed. However, the wearer should check for correct positioning of the cap before each episode.
- An additional contraceptive method should be used the first three times the cap is worn during intercourse (to ensure protection should the cap become dislodged). If dislodgement occurs, cap use should be discontinued and the cap should be refitted.
- The cap should not be used during menses.
- Refitting is necessary after abortion or childbirth.
- The cap should not be used in the presence of vaginal infection, discharge, pain, or odor. If these occur, medical evaluation is necessary.
- If lubrication is needed for intercourse, only water-based lubricants should be used. (Spermicide works well for this purpose.)
- The cap should be washed carefully after use with soap and water.
  If an odor develops, it can be soaked in vinegar or a cup of water
  with a teaspoon of lemon juice. Alternatively, the cap can be
  cleaned with a 25% bleach solution for 20 minutes, after which
  it should be rinsed thoroughly.
- A Pap smear should be taken 3 months after beginning use of the cap. If this is negative, then a Pap smear should be obtained every year thereafter.
- The cap should be replaced yearly (sooner if thin spots or tears occur). The patient should make an appointment with her physician to check if it still fits adequately.
- If the cervical cap is used properly, 6% of women will become pregnant after using the device for a year.
- If the device is left in too long, infections can occur, so the patient must follow the previously listed guidelines.

#### **Procedure**

- 1. Review the instructions from the FemCap kit.
- 2. Put on gloves and select the appropriate size of FemCap (described in the equipment section).
- Lubricate the edges of the device, compress it, and insert vaginally. The FemCap should be inserted with the long brim first and pushed into the vagina until the dome fits snugly over the cervix (Fig. 130-2).
- 4. The cap should cover the entire cervix and adhere to it by self-generated suction.
- 5. The rim of the cap should fit evenly around the circumference of the vaginal fornices.
- No gaps should be felt between the rim of the cap and the cervix.
- 7. Tug gently on the removal strap to guarantee that the cap will not dislodge.

<sup>†</sup>Based on limited-duration trials of second-generation FemCap.

**Figure 130-2** Proper placement and positioning of the FemCap. (Courtesy of FemCap, Inc., Del Mar, Calif; with permission.)

- 8. If the cap does not fit satisfactorily, try one of the other two sizes.
- 9. *Remove the cap* by gripping the strap and rotating the FemCap. Push on the dome to break the suction and pull the cap out using the strap.
- 10. Have the patient repeat the insertion and removal process to demonstrate understanding.

#### **Complications**

- Pregnancy is possible if the cap dislodges during intercourse. This
  was one of the major reasons women discontinued the firstgeneration cervical cap, although dislodgement is much less
  common with the second-generation FemCap. Counseling
  patients about emergency contraception and providing a prescription for emergency use may be a desired option for certain women
  (see Chapter 129, Emergency Contraception).
- Vaginal odor or discharge occurs in 5% to 27% of users.
- Vaginal or cervical lacerations and abrasions are possible if the cap is left in place too long.
- Vaginal discomfort occurs in less than 3% of users.
- Toxic shock syndrome is uncommon.

#### **Postprocedure Management**

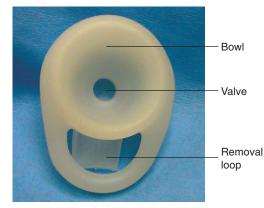

The patient should sit and also ambulate to ensure that the cap does not dislodge. No discomfort should be noted when the cap is correctly applied.

#### **Postprocedure Patient Education**

- The FemCap should be used with a one-quarter teaspoon of spermicide. Spermicide should be applied in the dome and spread over the brim.
- The FemCap must be placed before intercourse.
- The cap must be left in place for 6 hours after intercourse.
- It may be safely worn for up to 48 continuous hours.
- After removal, the FemCap should be washed with mild soap and water and allowed to air dry.
- FemCaps generally last approximately 1 year.

#### **SHIELD**

Lea's shield is a one-size silicone barrier (Fig. 130-3). It has a valve that allows for passage of cervical secretions while the shield is in place. The device was FDA approved in 2002; data on efficacy of Lea's shield are limited to one 6-month clinical trial. The 6-month pregnancy rate in this study was 5.6 per 100 when spermicide was

**Figure 130-3** Lea's shield. (Courtesy of Yama, Inc., Union, NJ; with permission.)

used and 9.3 per 100 without spermicide. Women who are parous have slightly higher failure rates with this method. Shield dislodgement occurs in less than 3% of users.

Although the shield does not require fitting by a medical provider, health care providers should be comfortable discussing use of the shield. Most women can learn how to insert and remove the shield by reading the user's manual.

#### **Anatomy**

Lea's shield has an elliptical bowl that fits over the cervix and acts as a reservoir for spermicide. It is held in place by its volume and the vaginal musculature.

#### Indication

Lea's shield is use to prevent pregnancy.

#### **Contraindications**

#### **Absolute**

- Allergy to silicone
- Vaginal delivery within the past 6 weeks
- History of toxic shock syndrome
- Others similar to cervical cap contraindications

#### Relative

- Breaks in the cervical or vaginal tissue
- Frequent urinary tract infections
- Genital tract infection
- Others similar to cervical cap contraindications

#### **Equipment and Supplies**

- Lea's shield
- Spermicide

#### **Preprocedure Patient Education and Forms**

Please refer to the patient education form available online at www. expertconsult.com.

#### **Procedure**

 Review the instructions for placement of Lea's shield. The shield is one size and does not require fitting by a medical provider. Most women can master insertion and removal of the shield after reading the Lea's shield user's manual.

- 2. The user should wash her hands with soap and water.
- 3. Coat the inside of the area around the bowl, the front rim, and the outer valve with spermicide.
- 4. Separate the labia with one hand and pinch the shield's rim.
- 5. With the thickest end first, insert the shield into the vagina. The valve should be facing out (down).
- 6. Push the shield up into the vagina as far as is comfortable.
- 7. The valve vents air and allows the shield to create a correct fit. The valve can be pressed to make sure all air is removed.
- 8. The removal loop should not protrude from the vagina.

#### **Common Errors and Complications**

- Three percent of users experience shield dislodgement; shield inversion occurs in 4% to 5% of users. A discussion of emergency contraception and a provisional prescription are helpful in cases of contraceptive failure.
- Failure to use spermicide may increase the rate of contraceptive failure.
- Increased frequency of urinary tract infections occurs in some shield users. Women should be encouraged to urinate before shield insertion and after intercourse.
- Shield removal before 8 hours after intercourse increases the failure rate. The shield should be left in place for a minimum of 8 hours.

#### Postprocedure Management

The patient should not feel discomfort with the shield in place. Have the patient ambulate and squat to ensure correct fit and placement of the shield. A 2-week follow-up after prescribing is recommended by the manufacturer.

#### **Postprocedure Patient Education**

- Shield position should be checked before each episode of intercourse to rule out dislodgement.
- The shield should not be used for more than 48 consecutive hours
- When removing the shield, grasp the loop with a finger, rotate to break suction, and pull the device out of the vagina.
- Thoroughly wash the shield with a mild soap for 2 minutes, air dry, and store in the provided pouch.
- Replace the shield annually.

#### **DIAPHRAGM**

Diaphragms were first produced in the United States in 1925, and current diaphragm design is not significantly different. Of the three models currently available, two are made of latex whereas the third is silicone. Contraceptive efficacy studies of newer barrier methods are usually judged against the diaphragm. Although diaphragms are traditionally used with spermicidal jelly, a recent Cochrane Review was unable to distinguish a difference in effectiveness when diaphragm use with spermicide was compared with diaphragm use alone.

Barrier contraceptive efficacy is highly dependent on proper and consistent use. Sixteen of 100 women using the diaphragm become pregnant annually with typical use. Perfect use of the diaphragm has a 6 per 100 failure rate.

#### **Indications**

- Pregnancy prevention
- Contraception for women with contraindications to other methods and who do not desire to be sterilized
- Desire for additional STI protection in combination with other contraceptive methods that do not confer protection

#### **Contraindications**

#### Absolute

- Latex or spermicidal jelly allergy/hypersensitivity
- Postpartum (<6 weeks)

#### Relative

- Vaginal stenosis or significant pelvic abnormalities
- Recurrent urinary tract infections
- Aversion to manipulation of the genitals
- Uterine prolapse
- Significant cystocele or rectocele

#### Equipment

- Diaphragms (sizes 65 to 90) are of three types:
  - Arching spring: Molded one-piece spring and firm-rimmed dome that form an arc when the rim is compressed in the center. It requires no introducer and is recommended for women with decreased pelvic support, cystocele or rectocele, or retroverted uterus, or for those who find a firmer rim easier to insert. This is the most popular type in the United States.
  - 2. Coil spring: Molded one-piece spring and dome with a softer, more flexible rim. It may be used with an introducer and is recommended for women with good vaginal support and no cystocele, rectocele, or pelvic floor relaxation; the cervix should be midplane or anterior.
  - 3. Flat spring: Molded one-piece spring and dome with a softer and more flexible rim than the arching spring or coil spring. It has flat-plane flexibility, may be used with an introducer, and is recommended for smaller women with a narrow or shallow pelvic shelf. It is excellent for nulliparous women or athletic women with strong pelvic musculature.
- Fitting ring kit. Kits can be obtained from most diaphragm manufacturers at minimal to no cost. The rings are graduated sizes that differ by increments of 5 mm. Fitting with domed rings provides a more realistic sensation for the patient as to how a diaphragm will feel (Fig. 130-4).
- Diaphragm introducer (optional).
- Spermicidal jelly (usually nonoxynol-9).

#### **Precautions**

- Poor vaginal tone, a shallow vaginal shelf, or a cystocele or rectocele may prevent effective use of the diaphragm.
- Refitting is often necessary after pregnancy, pelvic surgery, or weight gain of more than 15 pounds.
- Women with a latex allergy are candidates for the wide seal rim diaphragm (latex free).

#### **Preprocedure Patient Education and Forms**

Diaphragm fitting by a health care provider is required. The fitting process should be discussed with the patient. Efficacy rates and the

**Figure 130-4 Diaphragm fitting kit.** (Courtesy of CooperSurgical, Inc., Trumbull, Conn.)

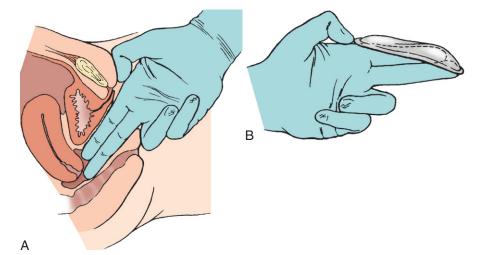

Figure 130-5 Clinical examination to determine proper diaphragm size. **A,** Insert the gloved index and middle fingers into the vagina, aiming for the posterior fornix with the middle finger. Mark the spot on the glove where the index finger touches the inferior pubic symphysis. **B,** Place the fitting ring or diaphragm over the end of the middle finger, and place the opposite side of the ring over the line marked on the gloved index finger.

proper and consistent use of the diaphragm should be stressed. Please refer to the patient education form available online at www. expertconsult.com.

#### **Procedure**

- 1. Place the patient in dorsal lithotomy (pelvic) position.
- 2. Don examination gloves and apply surgical lubricant to the index and middle fingers.
- 3. To estimate the size of the diaphragm, insert the gloved index and middle fingers into the vagina. Aim for the posterior fornix with the middle finger (Fig. 130-5A).
- 4. Note the spot where the index finger touches the inferior pubic symphysis.
- Mark this spot on the glove using either a marker or instrument, or your thumb.
- 6. Remove the fingers from the vagina.
- Place the fitting ring or diaphragm over the end of the middle finger.
- 8. Place the opposite side of the ring over the line marked on the gloved index finger (75 mm is a common size; Fig. 130-5B).
- Apply surgical lubricant to the outer surface of the fitting ring (only) that most closely approximates the determined diameter.
- 10. Fold this fitting ring in half by pressing the sides together with the thumb and fingers (Fig. 130-6A).
- 11. Insert the folded diaphragm vaginally while the other hand holds open the vulva. Direct the diaphragm toward the posterior fornix (Fig. 130-6B).

- 12. Check for correct positioning by feeling for the cervix through the dome of the fitting diaphragm or in the center of the fitting ring (Fig. 130-6C).
- 13. Gently manipulate the anterior rim until it rests directly behind the pubic symphysis.
- 14. Have the patient perform a Valsalva maneuver and squat to confirm the fit.
- 15. Remove the diaphragm by hooking the index finger up and around the anterior rim and pulling the diaphragm down and out through the introitus (Fig. 130-7).
- 16. The patient should demonstrate proper technique for both insertion and removal of the diaphragm. Check that the patient can feel the cervix through the diaphragm dome and confirm placement of the anterior rim behind the pubic symphysis.
- 17. Describe the proper application of spermicide to the diaphragm. One tablespoon of spermicidal jelly containing nonoxynol-9 is applied to the concave side of the dome (for use) in addition to around the rim.

#### **Common Errors**

- Improper fitting. A diaphragm that is too small does not lodge behind the pubic symphysis and falls out. An inappropriately large diaphragm protrudes out in front of the pubic symphysis.
- Failure to leave the diaphragm in place for a minimum of 6 hours after intercourse. Patients should be counseled not to douche or remove the diaphragm immediately after coitus.

**Figure 130-6 A,** Diaphragm is folded for insertion. **B,** Insertion of the folded diaphragm. **C,** Proper diaphragm position: The cervix is palpable behind the diaphragm (*a*); the rim fits snugly behind the symphysis pubis (*b*).

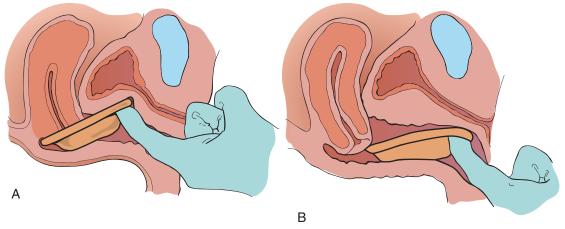

Figure 130-7 Removal of the diaphragm. A, Finger is hooked under the rim. B, Diaphragm is pulled through the introitus.

#### **Complications**

- Continuous diaphragm use for longer than 24 hours increases the risk of toxic shock syndrome (incidence of 2.4 per 100,000 women).
- Ulceration can result from excessive pressure of the diaphragm against the vaginal sidewalls with a poorly fitting device.
- Urinary tract infections are the most frequent side effect of diaphragm use.

#### **Postprocedure Patient Education**

- Patients should be shown and should practice diaphragm insertion and removal techniques, including how to apply spermicidal jelly to the rim and the dome. One tablespoon should be applied to the concave surface of the dome and the rim of the diaphragm so that the uterus is sealed off mechanically and chemically.
- Make sure that the diaphragm rim is firmly in place behind the pubic bone and below and behind the cervix. The patient should feel for the cervix through the dome of her diaphragm to ensure correct placement.
- Warn the patient not to douche or remove the diaphragm for 6 hours after intercourse. Leave the diaphragm in place and apply more spermicide if additional coitus occurs during this time.
- The patient should walk around the examination room with the diaphragm in place to ensure a comfortable fit.
- The diaphragm prescription should include the manufacturer's name, the type, and the size. A refill can be prescribed in case a new diaphragm is needed and the provider is unavailable.

Please refer to the sample patient education form available online at www.expertconsult.com.

#### **SPONGES**

The sponge is a nonprescription, single-use barrier contraceptive made of polyurethane foam impregnated with nonoxynol-9 spermicide. The concave side fits against the cervix, whereas the loop on the opposite side augments sponge removal. Although the Protectaid sponge is available in Canada, the Today Sponge is the only contraceptive sponge currently available in the United States (Fig. 130-8).

Sponges are sold in packs of three (\$7.50 to \$9). Effectiveness rate is 89% to 91% for perfect use and 84% to 87% with typical use. Parous women may have higher rates of failure than women who have not been pregnant. The sponge does *not* reduce the risk of STIs or HIV/acquired immunodeficiency syndrome (AIDS).

#### **Anatomy**

The sponge is inserted transvaginally and placed with the concave side covering the cervix.

#### **Indications**

- Prevention of pregnancy
- Contraception for women who are breast-feeding
- Birth control for women with contraindications to other methods or who need backup for the pill

#### **Contraindications**

#### Absolute

- Allergies to polyurethane, nonoxynol-9, or medications containing sulfa
- History of toxic shock syndrome
- History of recent delivery, miscarriage, or abortion (<8 weeks)
- Vaginal obstruction/anatomic abnormalities

#### Relative

- Current menstruation
- Active genital tract infection

**Figure 130-8** The Today Sponge. (Courtesy of Allendale Pharmaceuticals, Allendale, NJ; with permission.)

- Patient difficulty in understanding instructions for use
- Patient difficulty correctly inserting or removing the sponge
- Patient discomfort touching genitals

#### **Precautions**

The sponge offers no protection against STIs or HIV/AIDS.

#### **Procedure**

- 1. The patient should read the package insert before use.
- 2. Wash hands with soap and water.
- Wet the sponge with a minimum of two tablespoons of clean water.
- 4. Squeeze the sponge to help activate the spermicide.
- 5. Fold the sponge in half with the loop toward the outside.
- 6. Slide the folded sponge into the vagina and push it inside until the cervix is covered. The sponge will unfold.
- 7. Check sponge placement by sliding a finger around the edge to guarantee that it covers the cervix. The loop should be palpable.
- 8. Insert up to 24 hours before intercourse; the sponge must be left in place for 6 hours after intercourse.
- 9. Remove the sponge after 30 hours of continuous use.
- 10. *To remove*, insert a finger intravaginally and pull the sponge out using the loop.

#### **Common Errors**

- Failure to hydrate the sponge before use. The spermicide is most effective if the sponge is dampened with at least two tablespoons of water and then squeezed.
- Failure to place the correct side of the sponge directly against the cervix. After placement, check that the sponge edges are well applied against the fornices and that the loop is on the side that faces the vagina.

#### **Postprocedure Patient Education**

The sponge should be left in for a minimum of 6 hours after intercourse. It should not be left in place for longer than 30 continuous hours. Sponges are for one-time use only. Used sponges should be disposed of in a trash receptacle and not in a toilet.

#### MALE AND FEMALE CONDOMS

The *male condom* is a barrier contraceptive device that covers the penis and isolates sperm. It is unrolled onto the erect penis while leaving a space at the end to contain the ejaculate. Although most modern male condoms are made of latex, animal-product and polyurethane-based prophylactics are inexpensive and all are available without a prescription. The clinician should discuss appropriate use with patients because male condoms are frequently used incorrectly and patients are often reticent about asking questions. When combined with spermicide, pregnancy rates range from 2 to 10 pregnancies per 100 users per year. Male condoms serve as a barrier and can decrease the transmission of STIs.

The FC Female Condom is an over-the-counter, FDA-approved condom for women (Fig. 130-9). It is one size and does not require fitting. Made of soft, flexible polyurethane, it is a lubricated sheath with flexible rings on each end. The sealed ring is inserted into the vagina like a diaphragm, whereas the open ring rests against the vulva. Female condoms made of nitrile (FC2 condoms) are one-third the cost of the polyurethane condom, but are not available in the United States. Of 100 women who use female condoms, 21 become pregnant within 1 year with typical use; perfect use has a 5 in 100 failure rate.

Figure 130-9 The FC female condom. (Courtesy of The Female Health Company, Chicago, Ill; with permission.)

#### **Indications**

- Pregnancy prevention
- Prevention of STIs
- Adjunct to other contraception for STI prevention

#### **Absolute Contraindications**

- Allergy or hypersensitivity to latex (latex condoms)
- Allergy or hypersensitivity to spermicide (condoms containing spermicide)
- Allergy to polyurethane (female condom)

#### **Precautions**

The availability of emergency contraception should be discussed.

#### **Preprocedure Patient Education and Forms**

The female condom can be inserted up to 8 hours before intercourse but usually is inserted immediately before use. The FC2 condom is available over the counter and is for one-time use only. The cost is around \$2.50 per condom.

Please see the patient education form available online at www. expertconsult.com.

#### **Procedure (Female Condom)**

- 1. Detailed instructions for use are available in the product packaging.
- Squeeze the sides of the inner ring (closed end of condom) and insert it into the vaginal vault.
- 3. Push the inner ring until it encircles the cervix
- 4. Let the outer ring overlap an inch over the perineum.
- For condom removal, squeeze and twist the outer ring to keep semen from leaking out. Pull the condom from the vagina and dispose of it in the trash.

#### **Common Errors**

- Condom efficacy is decreased with use of certain lubricants or oil-based compounds (Box 130-1).
- Use of old/dated condoms may result in contraceptive failure.
   Keep condoms properly stored and use by the expiration date printed on the wrapper.

## Box 130-1. Common Oil-Based Preparations that Adversely Affect Condom Efficacy

Baby oil

Butoconazole (Femstat)

Butter

Cocoa butter

Cold cream

Conjugated estrogens (Premarin)

Estradiol (Estrace)

Hand lotion

Lubricants

Medications

Miconazole (Monistat)

Mineral oil

Petroleum jelly Hand lotion

Shortening

Suntan oil

Tioconazole (Vagistat-1)

Vegetable oil

#### **Complications**

Vaginal irritation with female condom use.

 Condom rupture can result in pregnancy. Emergency contraception may be considered if the risk of pregnancy is high (see Chapter 129, Emergency Contraception).

 Hypersensitivity or allergy to latex or polyurethane. Male and female condoms made from plastic or nitrile are an option.

# BARTHOLIN'S CYST AND ABSCESS: WORD CATHETER INSERTION, MARSUPIALIZATION

Michael L. Tuggy

Bartholin's glands are located at the vaginal opening between the hymenal ring and labia minora (at approximately the 5 and 7 o'clock positions). Simple incision and drainage (I&D) of a Bartholin's duct cyst or gland abscess may give immediate results with significant pain relief, but recurrence after such a procedure is common. Bartholin's cysts and abscesses are best treated using a *Word catheter* to induce the formation of an epithelialized tract from the *vulvar vestibule* to the cyst. This allows continued functioning of the Bartholin's gland, proper drainage, and minimal recurrence. The recurrence rate using this technique is between 2% and 15%. The Word catheter has a short latex stem with an inflatable bulb at the distal end (Fig. 131-1) and can be used for both conditions.

For patients with noninflamed and recurrent Bartholin's cysts, *marsupialization* is a permanent cure. The procedure can be performed in the office but often is done as a same-day surgical procedure. It is very well tolerated by patients, with a rapid healing time and minimal postprocedure discomfort. Complications are rare and the technique is easily learned, especially by those physicians familiar with perineal repairs.

#### **INDICATIONS**

- Treatment of symptomatic Bartholin's duct cyst (painful, growing)
- Treatment of Bartholin's gland abscess

#### **CONTRAINDICATIONS**

Any condition that would preclude normal I&D of a vulvar cyst or abscess would preclude use of the Word catheter. Small, asymptomatic glands do not need to be drained.

**Figure 131-1** Word catheter (bottom). 3-mL syringe filled with water and 25-gauge needle (middle). Word catheter inflated with water (top).

#### **EQUIPMENT**

- Word catheter (Rusch and Milex; most medical suppliers will have on hand)
- 3-mL syringe (for catheter inflation)
- 22-gauge, 1-inch needle (for catheter inflation)
- 2% lidocaine for anesthesia, usually with epinephrine
- 30-gauge, 1½-inch needle (for anesthesia)
- 3-mL syringe (for anesthesia)
- No. 11 blade
- Pickups with teeth
- Small hemostats (two)
- 4 × 4 gauze pads
- Normal saline for irrigation
- Antiseptic solution (povidone-iodine if not allergic)
- 4-0 Vicryl suture (if marsupialization is done)

#### PREPROCEDURE PATIENT EDUCATION

The clinician should explain the procedure to the patient and obtain informed consent. A non-narcotic oral analgesic may be administered before the procedure, if desired.

#### **PROCEDURE**

#### **Word Catheter Placement**

- 1. Place the patient in the dorsal lithotomy position.
- 2. Prepare the labia and vagina with the antiseptic solution. It is preferable to enter the cyst (Fig. 131-2A) or abscess from the vaginal side of the introitus unless this would require a much deeper incision (Fig. 131-2B). Inject lidocaine over the intended site of entry. If the incision is to be made external to the introitus where the abscess is "pointing," plan to insert the catheter approximately in the area of the original duct orifice, immediately adjacent the hymenal ring (Fig. 131-2C).
- 3. Lance or incise the cyst or abscess with a no. 11 scalpel blade (see Fig. 131-2C). It is essential that the stab wound penetrate the cyst or abscess wall, which will be evidenced by the free flow of pus or mucus. *Culture* contents if indicated. Although the majority of simple cysts are sterile, abscesses are typically

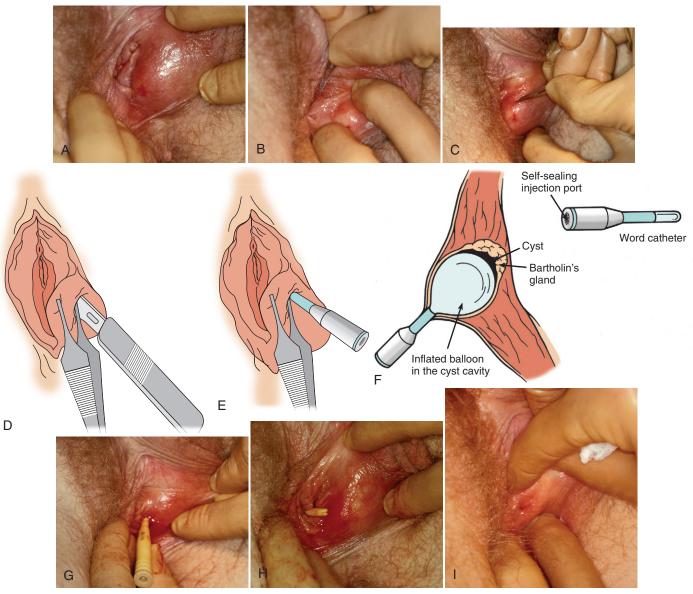

Figure 131-2 Insertion of Word catheter. **A,** Bartholin cyst after local anesthetic has been injected superficially. **B,** No. 11 blade points to ideal location inside the hymenal ring for the incision. However, the cyst is more prominent externally, so incision will be made there. **C,** Incising the cyst. Make the opening just large enough for the uninflated Word catheter tip to enter. **D,** Slide Adson forceps with teeth along the blade (which is in the cyst/abscess) and gently grasp the tissue. This will define the tract into the cyst. If this is not done, especially in smaller cysts, a false cavity may be created when inserting the catheter. **E,** The blade is removed but the forceps are kept in place. Insert the catheter along the forceps. **F,** Remove the forceps. Inflate the balloon with saline. Gently tug the catheter after inflation to ensure it does not fall out of the opening. **G,** Balloon is inflated within the cavity of the cyst so that it will not fall out through the stab wound. **H,** Tuck the exposed portion of the catheter into the vagina. **I,** Appearance of the area immediately after removal of the catheter.

polymicrobial, and many others contain *Neisseria gonorrhoeae*. Culture usually will not change initial management. The stab wound must be *just large enough* for the catheter to be inserted, usually 3 to 4 mm.

It may be difficult to insert the catheter into the cyst cavity if the incision is made, the contents are extruded, and the cyst/abscess has collapsed. Attempting to insert the catheter blindly may create a false tract and the catheter may not be in the cyst/abscess itself, which is necessary. To avoid creating a false tract and to ensure proper placement of the catheter, incise carefully through the skin until the cyst/abscess fluid drains. Before removing the blade, but after the incision is made, insert pickups (with teeth) down the side of the blade into the lumen and grasp gently (Fig. 131-2D). This stabilizes the tissue and identifies the cavity. Remove the blade. Insert the Word catheter (Fig. 131-2E).

- 4. Once inserted, inflate the catheter bulb by injecting 3 mL of saline through the sealed-stopper end (Fig. 131-2F). Use just that quantity of saline necessary to ensure that the catheter will not fall out with normal activity (usually 2.5 to 3 mL). Do *not* use air to inflate the catheter. Remove the pickups (Fig. 131-2G).
- 5. If the incision was made inside the hymen, tuck the catheter stem into the vagina, where it will rest perpendicular to the perineum (Fig. 131-2H). With the catheter in the vagina, the patient has freedom of movement and activity without the added awareness of protrusion of the catheter stem, which can occur if an external incision site is used. Most patients tolerate the catheter without discomfort if excessive amounts of saline are not introduced into the catheter bulb.
- 6. The catheter can be removed after withdrawing the saline in 4 to 6 weeks, leaving a small ostium for the gland (Fig. 131-2I).

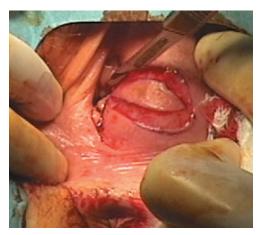

Figure 131-3 Incision for marsupialization on vaginal sidewall (retracted).

The gland may eventually scar shut, which has no adverse consequences.

#### Bartholin's Cyst Marsupialization

- Place the patient in the dorsal lithotomy position. Block the incision site with local anesthetic with 2% lidocaine with epinephrine or use a pudendal block with 2% lidocaine without epinephrine. Some patients may prefer spinal or general anesthesia, but this requires the procedure be done in a same-day surgery center.
- 2. Clean the perineum with povidone–iodine solution (if not allergic).
- 3. Inspect the external genitalia to determine the extent of the duct cyst. Retract the labium laterally to identify the incision site internal to the hymeneal ring. Make the incision longitudinal with respect to the vagina (Fig. 131-3). Incisions can also be done following the circumferential folds of the vaginal mucosa, but lack the natural tension of the mucosa and could lead to premature closure and incomplete marsupialization. Generally, a fusiform incision 1 or 2 cm in width at the center is needed to allow for removal of a substantial portion of the Bartholin's cyst wall. Avoid excising any portion of the external skin (vs. mucosa).
- 4. Usually during this excision of the ellipse, the cyst contents and the cyst wall will collapse. Therefore, the mucosa over the cyst should be excised first and the cyst wall grasped with two small hemostats before the segment is removed. Explore the cyst with small hemostats and remove any loculated portions of the cyst. Patients older than 40 years of age are at higher risk for cancer in Bartholin's gland, so look for signs of neoplastic-appearing epithelium in the cyst (Fig. 131-4).
- 5. Thoroughly irrigate the cyst cavity with normal saline.

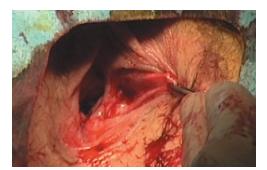

Figure 131-4 Bartholin's cyst opened with roof removed.

Figure 131-5 Marsupialized Bartholin's cyst with sutures in place.

- 6. When suturing the Bartholin's cyst wall, approximate the cut edge of the cyst wall to the adjacent edge of the vaginal mucosa. This allows for more rapid transformation of the Bartholin's cyst wall into a normal mucosal lining that will blend into the vaginal mucosa. Use 4-0 Vicryl and place interrupted sutures around the excisional margins.
- 7. Place an anchoring stitch with long tags proximally to grasp and stabilize the tissue. Pass the stitches from the inside through just the Bartholin's cyst wall. Bring the needle to the surface between the cyst wall and submucosal layer. Now insert the needle under the vaginal epithelium and pull it to the surface of the vaginal wall. This effectively imbricates the two layers (cyst wall and vaginal mucosa) over the submucosal tissue, which allows them to heal together (Fig. 131-5). The intent is to suture the cyst cavity open.
- 8. After the entire site has been sutured open, irrigate the wound and inspect it for bleeding. There should be a gap of at least 1 cm across the open marsupialization. Normally no dressing is needed. A pad is placed to allow for collection of blood or drainage from the wound.
- 9. Instruct the patient to perform sitz baths daily for 3 or 4 days and to return for follow-up in about a week (see the postoperative patient handout available online at www.expertconsult.com). At that time, the cavity will be probed for patency. Use of prophylactic antibiotics is unnecessary in most cases and the need should be assessed individually. Excessive induration in the local tissue or risk factors for infection, such as pregnancy or diabetes, may prompt the need for antibiotic therapy. Sutures will absorb without further intervention.

#### **COMMON ERRORS**

- Creating a false tract for the catheter placement (see earlier).
- Catheter falls out before it is time to be removed. This may lead to recurrence of the cyst/abscess. The error occurs after the balloon is inserted into the cyst/abscess and after the fluid is injected into the balloon (but the syringe is still in the port), when the clinician releases the pressure on the syringe plunger to check the tightness of the balloon in the cavity by tugging on it. Although it may seem secure then, the increased pressure in the balloon will push some saline back up into the syringe (unless pressure is maintained on the plunger). The balloon then in effect deflates to a smaller size and the catheter may inadvertently fall out prematurely. To prevent this from occurring, maintain pressure on the syringe plunger while checking the bulb placement and snugness in the cavity. The catheter could also fall out because of too large of a stab wound.

- Continuous pain after insertion of the Word catheter may occur.
  The bulb may be too large for the cyst cavity, which may be corrected by withdrawing some of the fluid, thus reducing the size of the bulb. Also, if the bulb is not in the true cavity but in the space between the fascia and the cyst wall, the patient will complain of significant pain. In this case, catheter removal and reinsertion will need to be repeated under local anesthesia.
- With an abscessed Bartholin's gland, there may be cellulitis around the vulvar opening of the duct. Insertion of the catheter may not correct the cellulitis and antibiotics may need to be administered for 48 to 72 hours after insertion of the catheter. If N. gonorrhoeae is cultured, appropriate actions need to be taken.
- If the needle used to introduce the saline into the catheter punctures the stem, the catheter will gradually deflate and fall out before epithelialization is complete.
- If the stab wound is too large, the catheter will fall out. It may
  be necessary to suture the stab wound around the catheter to keep
  it in place. If the catheter falls out in less than 4 weeks, the
  likelihood of recurrence is high. Because of only partial formation
  of a new tract, placement of another Word catheter is indicated,
  but it may not be possible because of constriction of the opening.

#### **COMPLICATIONS**

- Excessive bleeding (rare)
- Discomfort (usually only a few days)
- Recurrence
- Scarring (usually minimal)
- Infection
- Premature expulsion of the catheter

#### POSTPROCEDURE PATIENT EDUCATION

#### **Word Catheter**

- Tell the patient to expect a discharge because the catheter will allow for drainage of the cyst or abscess.
- The Word catheter is left in place for 4 to 6 weeks until epithelialization of the new tract is complete.
- Advise the patient that sexual activity may be resumed after 2
  weeks, but it may increase the risk of expulsion of the catheter.
  If this happens, another catheter may need to be inserted. It is
  best to defer sexual activity until the catheter is removed.
- Encourage daily showers or tub baths.
- Schedule a return visit in 4 to 6 weeks. At that time, the catheter is removed by inserting a needle into the catheter sealed-stopper end and drawing out the saline. The catheter is then withdrawn from the incision.

#### **Marsupialization**

- Daily sitz baths are encouraged for 3 to 5 days.
- Avoid sexual activity until after the first postoperative check at 1 week, although waiting for an additional week would be most prudent to allow for more complete healing.

### **BREAST BIOPSY**

Helen A. Pass

An excisional breast biopsy is a technically straightforward outpatient procedure readily performed under local anesthesia. With appropriate training and experience, primary care physicians can become qualified to perform most simple breast biopsies. The challenge is to correctly identify which lesions are amenable to biopsy and which require referral to a breast (general) surgeon. The goals in the management of a patient with a breast mass should be to obtain the diagnosis in the most expedient manner, to achieve good cosmesis, and to preserve all therapeutic options if the mass is unexpectedly found to be malignant at biopsy.

The only definitive method for ensuring that a mass is benign is to remove tissue for pathologic examination. The missed or delayed diagnosis of a breast mass that ultimately proved to be cancerous is currently the most litigious aspect of medical practice. Failure to be impressed with physical examination findings was cited as the most common reason for the delay in the diagnosis of breast cancer. Benign masses are usually smooth, well circumscribed (round), and freely mobile; however, many cancers (e.g., colloid, medullary, and expansive intraductal) may mimic this presentation. Similarly, even though the incidence of breast cancer rises dramatically after age 65 years, 63% to 80% of lawsuits resulted from the missed diagnosis of cancer in women younger than 50 years of age. In addition, whereas the presence of a significant positive family history increases the suspicion that a palpable abnormality may prove to be malignant, two thirds of all women with the diagnosis of breast cancer have no identifiable risk factor. Nevertheless, it is important to remind our patients and ourselves that not all breast masses are cancerous.

The role of mammography in women with a breast mass is twofold. First, it can offer clues as to the degree of suspicion that the mass may be malignant. Worrisome mammographic features include the findings of a spiculated lesion, a mass associated with pleomorphic microcalcifications, or dermal edema and retraction. Second, it allows assessment of the remainder of the breast parenchyma in both the involved and contralateral breasts. Before proceeding with excisional biopsy, a baseline mammogram must be obtained to rule out the presence of an occult synchronous lesion that may alter the surgical approach. Moreover, if the mass is highly suspect, referral to a surgeon may be indicated to facilitate management of a presumed breast cancer. It is crucial to realize that failure of mammography or ultrasonography to visualize a discrete, palpable abnormality should not be construed as evidence of the benignity of the lesion. Up to 10% of breast cancers are radiographically occult. Thus, a lesion should be removed if it meets the criteria for biopsy based on the clinical breast examination, regardless of the breast imaging characteristics. Likewise, if a woman identifies an area of change in her breasts, the complaint should be taken seriously.

In addition to highly suspect lesions, referral to a breast (general) surgeon should be considered for an additional small subset of patients. Masses in prepubertal or pubescent girls (prepubertal gynecomastia) could represent the forming breast buds and must not be sampled for biopsy unless highly suspect because lifelong cosmetic deformity may result. Masses greater than 4 cm are best approached by core biopsy provided that if the lesion proves to be malignant,

consideration should be given to neoadjuvant chemotherapy. In addition, if the lesion is benign, special surgical techniques will be necessary to minimize the cosmetic deformity associated with subsequent removal. Finally, biopsy of lesions requiring preoperative mammographic localization with wire placement should be performed by physicians who have received specific training in this technique.

Consideration should be given to performing fine-needle aspiration (FNA) before core or excisional biopsy (see Chapter 226, Fine-Needle Aspiration Cytology and Biopsy). FNA is both diagnostic and therapeutic for simple cysts, thereby avoiding unnecessary anxiety and surgery. If the mass is solid, a specimen for cytologic examination can be obtained, and breast cancer can be diagnosed before excisional biopsy. The false-negative rate of FNA is 0.4% to 35% and the false-positive rate is less than 1%. Thus, concordance among the clinical breast examination, the breast imaging, and the FNA (the triple test) must be established, especially if the decision is made not to proceed to biopsy.

#### **ANATOMY**

Anatomically, the breast extends superiorly to the level of the clavicle, inferiorly to the sixth or seventh rib, medially to the lateral border of the sternum, and laterally to the border of the latissimus dorsi muscle. The glandular structure sits atop the pectoralis major muscle, and deep breast biopsies may extend to the level of the fascia. The blood supply originates from the internal mammary, axillary, and intercostal arteries. The venous outflow parallels this arterial supply. The only innervation to the breast is cutaneous, extending from the plexus of nerves in the neck for the superior half of the breast and the intercostal nerves for the lower half of the breast. There is no direct innervation to the glandular structure. The lymphatic vessels in the breast drain to the axilla and the internal mammary lymph nodes.

In the center of the breast is the *nipple and areolar complex*. Surrounding the edge of the areolar complex are Montgomery tubercles, which provide lubrication important for breast-feeding.

The breast mound itself is composed of fat and glandular milk-producing tissue. About 15 to 20 ducts converge to exit the nipple. Cooper's ligaments run from the deep fascia to the dermis, traversing the breast gland and serving as suspensory ligaments of the breast. The lack of named structures within the breast glandular tissue simplifies breast biopsy because hemostasis usually is readily achieved with electrocautery. Except with circumareolar incision placement, numbness is rare in the peri-incisional area.

#### **INDICATIONS**

- The presence of a palpable, dominant abnormality in a male or female patient
- A cystic lesion if
  - The FNA contained bloody fluid
  - A palpable abnormality remains after FNA
  - The cyst recurred after two FNAs

- After an FNA that was equivocal, nondiagnostic, or not concordant with the clinical breast examination or breast imaging
- Unresolved patient anxiety and a desire for removal of the mass
- Physician uncertainty about the true nature of the lesion

#### **CONTRAINDICATIONS**

#### Relative

- Mass that is highly suspect for breast cancer (refer to breast or general surgeon)
- Mass greater than 4 cm (consider diagnosis by core biopsy or referral to surgeon)
- Mass in a prepubertal or pubescent female (consider referral)
- Lesion requiring preoperative mammographic localization (i.e., it is nonpalpable; consider referral)

#### **Absolute**

Uncorrected bleeding disorder or other unstable medical condition is an absolute contraindication.

#### **EQUIPMENT AND SUPPLIES**

- Surgical marking pen
- Povidone-iodine or other antiseptic skin preparation solution
- Fenestrated drape
- Local anesthetic (the addition of 1 mL of 8.5% sodium bicarbonate solution to each 10 mL of 1% lidocaine without epinephrine creates a buffered solution with a more neutral pH, allowing less discomfort during infiltration and a more rapid onset of action)
- Sterile 4 × 4 gauze
- Scalpel with no. 15 blades
- Two curved hemostats
- Needle driver
- Adson pickups
- DeBakey pickups (optional)
- Metzenbaum tissue scissors
- Allis clamp
- Small self-retaining retractor (e.g., mastoid retractor or small Weitlaner retractor) (optional)
- Army-Navy or Senn retractor
- Electrocautery unit
- 3-0 or 4-0 Vicryl suture
- 4-0 or 5-0 Monocryl or polydioxanone suture
- Steri-Strips or Dermabond
- Jobst postoperative brassiere (optional)

#### **PRECAUTIONS**

Immediately before any planned procedure, the woman must be examined. The surgeon must verify with the patient that the palpable abnormality still persists, concur on its location, and mark it with indelible ink. As with any surgical procedure, standard presurgical clearances and permits should be obtained.

#### PREPROCEDURE PATIENT PREPARATION

All women older than 30 years of age should have a preprocedure mammogram. Provide calm reassurance to the patient because the discovery of a breast mass and the knowledge that biopsy is necessary is a highly stressful event for the patient. Provide detailed explanations of the procedure supplemented by written educational material.

#### **PROCEDURE**

The abnormality should be identified and marked before the procedure with the patient's assistance. Determining the optimal place-

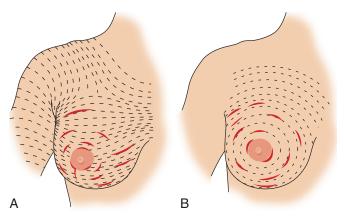

Figure 132-1 Proper planning of incisions limits postoperative scarring. See text for details.

ment of the incision for an excisional breast biopsy is a balance between achieving the most desirable cosmetic result and preserving further surgical options should the lesion prove to be cancerous. Use of preoperative FNA or core biopsy can minimize the number of breast masses unexpectedly found to be malignant. Generally, incisions placed along Langer's lines—the natural lines of skin tension and creasing—produce the best cosmetic result (Fig. 132-1A). However, a radial incision may be preferable in the most medial part of the breast (much easier to reexcise if a mastectomy is subsequently required) or in the lower half of the breast if the mass is larger, or subsequent removal of skin will be required (e.g., with reexcision lumpectomy; Fig. 132-1B). A better cosmetic result is achieved in the lower half of the breast by narrowing the breast when removing breast volume through a radial incision than by shortening the distance between the areolar complex and inframammary fold with a curvilinear incision. In a young woman in whom the mass is likely benign, consideration may be given to placing the incision in a circumareolar location.

Benign lesions may either be enucleated or removed with a small rim of normal tissue. Care should be taken to ensure that the mass is not morcellated. The specimen should be oriented for pathologic examination in case it is found to be malignant and reexcision is necessary.

After removing the breast mass, most surgeons no longer reapproximate the remaining deep breast parenchyma ("dead space"). This eliminates the breast distortion with poorer cosmesis and greater mammographic distortion that occurs when the "dead space" is reapproximated. Meticulous hemostasis must be achieved to avoid hematoma formation. Drains should *not* be used. Closure of the superficial fascia provides good restoration of the breast contours. The skin is then closed in a subcuticular fashion.

- 1. Obtain written informed consent.
- 2. Using sterile technique, cleanse and drape the breast.
- 3. Using a surgical marking pen, outline the incision and the borders of the mass (Fig. 132-2).
- 4. Give local anesthesia (1% lidocaine without epinephrine mixed 10:1 with 8.5% sodium bicarbonate). Infiltrate the incision with the local anesthetic to create a dermal wheal. Use the anesthetized wheal for all subsequent needle inserts, and infiltrate circumferentially around the lesion to be removed. Excess local anesthetic directly overlying the mass may obscure palpation of the nodule, hindering identification. (Alternatively, do a field block by injecting circumferentially around the lesion but not over the lesion itself. This allows easier palpation of the mass in the center of the field without the distortion created by the volume of anesthetic [Fig. 132-3].)
- 5. Incise the skin with a no. 15 blade, making sure to hold the blade at right angles to the skin edges to avoid beveling

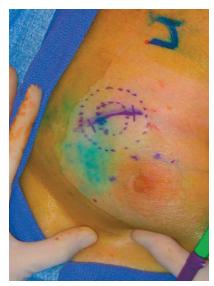

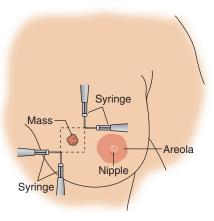

Figure 132-2 Palpable lesion marked for biopsy.

- 6. Use tissue scissors or cautery to dissect down to the level of the mass (Fig. 132-4).
- 7. Cauterize bleeders with the electrocautery.
- 8. Circumferentially excise the specimen using the tissue scissors, a no. 15 blade, or the electrocautery unit (Fig. 132-5). Exercise care to avoid harming the skin edges. An Allis clamp may be used on the mass to provide countertraction, facilitating removal of the mass. Provide more local anesthesia in the deeper layers as needed).
- Orient the specimen for pathologic evaluation using marking sutures (this can facilitate localization of inadequate margins should the lesion be found to be an incompletely excised malignancy).
- 10. Submit all specimens for pathologic evaluation. Use of frozensection analysis is optional because hormone receptor analysis is now routinely performed on paraffin-embedded tissue in case of malignancy.
- 11. Obtain meticulous hemostasis with electrocautery.

**Figure 132-3** Field block local anesthesia technique to preserve the ability to palpate the lesion in the center of the field. Infiltration of excessive amounts of local anesthetic directly over the mass makes palpation of the abnormality difficult.

Figure 132-4 Dissection with electrocautery.

- 12. Reapproximate the subdermal tissue with buried interrupted Vicryl sutures. To prevent deformity, do not reapproximate the deep tissues, and do not incorporate excessively large amounts of tissue because this may lead to dimpling (Fig. 132-6).
- 13. Close the skin with a running subcuticular suture of 4-0 or 5-0 Monocryl or polydioxanone (Fig. 132-7).

#### SAMPLE OPERATIVE REPORT

See the sample operative report online at www.expertconsult.com.

#### **COMMON ERRORS**

- Failure to sample a palpable, dominant mass because the lesion is radiographically occult
  - Resolution: Because up to 10% of cancers can be radiographically occult, biopsy must be performed if clinical examination confirms the presence of a dominant mass.
- Failure to obtain a mammogram before biopsy
   Resolution: All women older than 30 years of age should have a
   recent mammogram before biopsy to rule out the presence of
   occult synchronous lesions that may modify the surgical
   approach.
- Poor orientation of the surgical incisions
   *Resolution*: Proper planning can ensure a better cosmetic outcome
   and allow for subsequent surgery if malignancy is identified
   (see Fig. 132-1).

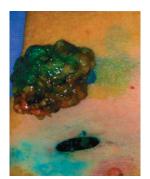

Figure 132-5 Lesion excised.

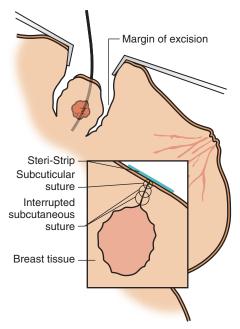

Figure 132-6 Schema for closure technique.

#### COMPLICATIONS

- Hematoma (may mimic recurrence of the mass)
   Resolution: (1) Confirm patient does not have an unsuspected
  - bleeding diathesis. (2) If the hematoma is symptomatic, reoperate with evacuation of the hematoma. Search for and cauterize or ligate of any site of bleeding. Use a compressive dressing. (3) If asymptomatic, reassurance, use of a supportive brassiere, and passage of time will allow spontaneous resolution.
- Infection (cellulitis or abscess formation)
  - Resolution: Seroma aspiration can differentiate between cellulitis and cellulitis with abscess formation (send fluid for Gram stain, culture, and sensitivity even if the fluid is clear). Cellulitis without abscess formation usually responds to oral antibiotic therapy. Resolution is usual with the use of a first-generation cephalosporin. If no response is obtained in 7 to 10 days, culture and sensitivity data may be helpful. For cellulitis with abscess formation, drainage of the abscess is necessary. Complete aspiration under ultrasonographic guidance and initia-

**Figure 132-7** Cosmetic closure: appearance on completion of the surgery.

- tion of oral antibiotic therapy may be tried initially. If abscess recurs, drain placement with or without surgical evacuation and irrigation may be necessary. Again, culture and sensitivity data can help with antibiotic selection.
- Scarring or skin distortion
  - Resolution: Be sure the patient understands that a fine scar should be expected. If the patient tends to form hypertrophic or keloid scars, a small amount of triamcinolone (10 mg/mL) can be used with the local anesthesia in the incision tract. Avoid scarring with appropriate preoperative planning. After surgery, silicone sheeting, Mederma cream application, or cross-scar massage may improve appearance of scarring.
- Pain (usually minimal)
  - Resolution: The use of oral analgesics, use of supportive brassiere, and topical application of ice or heat should provide adequate relief.
- Fluid collection (seroma)
  - *Resolution:* May require aspiration but only if symptomatic. The presence of an asymptomatic seroma is *not* an indication for drainage.
- Failure to identify the correct mass or incomplete removal of the
  - Resolution: Can be avoided by proper preoperative localization, marking, and patient confirmation. Before closure, palpate the biopsy bed to confirm the absence of residual palpable abnormality. If it is recognized after surgery, prompt reoperation is indicated.
- Need for subsequent surgery
- Resolution: If the mass is malignant or incompletely excised, promptly refer to a breast (general) surgeon.

#### POSTPROCEDURE MANAGEMENT

Wash off any remaining skin preparation solution, and then apply Steri-Strips and a sterile bandage or use a cyanoacrylate surgical glue (e.g., Dermabond [Ethicon, Somerville, NJ]). If adequate hemostasis has been ensured, there is no need for bulky, pressure dressings. A surgical brassiere may be used to enhance postoperative comfort.

The patient must be provided with prescriptions for adequate analgesia by mouth, emergency phone numbers, and written post-operative instructions.

The patient may remove the dressing in 24 to 48 hours and resume showering. If Dermabond or Opsite (Smith & Nephew, London) is used over gauze-covered Steri-Strips, the patient may shower immediately. Submersion of the incision (e.g., swimming) and vigorous exercise should be avoided for 1 week. The sutures will dissolve and should not require removal.

#### **POSTPROCEDURE PATIENT EDUCATION**

Give the patient written instructions regarding removal of the dressing, resumption of showering, and follow-up appointment. The patient should report excessive pain, drainage from the wound, redness, fever, or abnormal swelling. A follow-up appointment will ensure the lesion has been removed, although induration may be palpable for several weeks. See the patient education form online at www.expertconsult.com.

#### **SPECIAL CONSIDERATIONS**

- The appearance of the incision is all the patient sees; your surgical skill will be judged by the scar left on the breast. Plan the incision carefully and use plastic surgical technique for skin closure.
- It is imperative to communicate the pathology results in a timely manner and to refer to specialists if necessary.
- Avoid biopsy of large or complicated lesions; refer instead.

 Management of breast complaints is very litigious. Adequately document the work-up. Obtain informed consent. Diligently follow up all biopsy results, and recognize when referral is appropriate.

#### **CONCLUSION**

Accurate interpretation of the clinical breast examination can be difficult. Any persistent palpable abnormality or asymmetric finding must be evaluated with physical examination, breast radiologic imaging (mammography or ultrasonography), and tissue diagnosis. All findings must be concordant; if they are not, work-up must proceed even if the mammogram is negative. With sufficient training and experience, most primary care practitioners can perform excisional breast biopsies in the office setting expeditiously and with a good cosmetic outcome. Complex or highly suspect masses may prompt referral to a breast specialist.

## CERVICAL CERCLAGE

Madeline R. Lewis • Mark Lewis

Cerclage is a procedure designed to manage cervical insufficiency, which is defined as a painless dilation of the cervix with expulsion of the products of conception in the second or early third trimester. Most often cerclage is used to prevent preterm deliveries in women with a history of previous second-trimester pregnancy losses or known shortened cervices.

The incidence of cervical insufficiency is uncertain because of the lack of clear diagnostic criteria and inadequate reporting methods. The success rate of cerclage is also difficult to assess owing to a paucity of adequate data. Available studies suggest a 75% to 90% success rate with cerclage when used in a subsequent pregnancy after recurrent pregnancy loss.

There are several different cerclage techniques; the most common and simplest is the McDonald procedure. Other techniques include the Shirodkar cerclage and transabdominal approaches. The McDonald cerclage involves inserting a pursestring stitch at the cervicovaginal junction using monofilament suture. This procedure is best done as an elective procedure but may also by used in an urgent or emergent setting.

American College of Obstetricians and Gynecologists (ACOG) guidelines recommend performing an elective cerclage at 14 to 16 weeks' gestation after verifying fetal life by ultrasonography. The cerclage is removed after the 37th week of pregnancy or the onset of premature labor.

#### **ANATOMY**

The relevant anatomy is shown in Figure 133-1. The area of importance is the proximal cervix, near the area where the cervix meets the vaginal wall. The orientation of the cervix is important, and this chapter uses the clock method of describing locations on the cervix. This method assumes that the patient is in the dorsal lithotomy position and that the anterior cervix is defined as 12 o'clock.

#### **INDICATIONS**

Cervical insufficiency may be due to many factors. Cerclage may be considered for all. Indications include the following:

- Most frequently, a history of cervical insufficiency that resulted in three or more unexplained second-trimester pregnancy losses or preterm labor. When possible, medical records from these pregnancies should be carefully reviewed to verify cervical insufficiency.
- Surgical trauma from cone biopsy, loop electrosurgical excision procedure, obstetric laceration, or overdilation during pregnancy termination.
- Congenital anomalies of the patient.
- Cervical length abnormalities (e.g., foreshortened cervix).
- Deficiencies in cervical collagen and elastin.
- In utero diethylstilbestrol exposure.
- Funneling of amniotic membranes into the cervical canal on ultrasonography.

 Placenta previa if associated with cervical dilation. Some advocate the use of cerclage with placenta previa alone, but this has not been shown to prolong pregnancy in these patients. Cerclage is not contraindicated in patients with placenta previa who otherwise should have the procedure performed.

#### **CONTRAINDICATIONS**

#### **Absolute**

- Nonviable pregnancy
- Undiagnosed vaginal bleeding
- Ruptured membranes
- Active preterm labor
- Acute cervical or intrauterine infection

#### Relative

- Known or suspected abnormal pregnancy
- Prolapse of fetal membranes through the external cervical os (higher risk of iatrogenic rupture of membranes)

#### **EOUIPMENT AND SUPPLIES**

Cerclage is considered an outpatient procedure and is performed in the operating room. Sterile preparation and proper drapes and equipment are necessary. Specific instruments include the following:

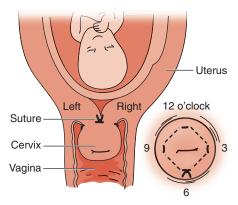

- Bladder catheter
- Weighted vaginal speculum
- Retractor (Deaver or right-angle)
- Ring forceps
- Nonabsorbable suture material (no. 5 Mersilene band, Ethibond; not to be confused with a 5-0 suture, which is much smaller) and curved needle
- Pickups
- Metzenbaum scissors
- Needle driver

#### **PRECAUTIONS**

Be aware that an urgent or emergent cerclage will have an increased incidence of complications. A cerclage is best performed in a scheduled setting with clear indications. Be certain to confirm a viable pregnancy before starting the procedure.

#### PREPROCEDURE PATIENT EDUCATION

- Inform patient that there are few data to prove the exact benefits and risks of the procedure.
- Review the risks of the procedure with the patient:
  - Rupture of membranes (may be up to 65% within 2 weeks)
  - Chorioamnionitis (may occur in up to 30% of cases)
  - Suture displacement

**Figure 133-1** Cervical cerclage and relevant anatomy. Note that the initial suture is placed at 6 o'clock to allow the knot to reside in the posterior vagina.

- Uterine rupture
- Maternal septicemia
- Preterm labor and delivery
- Fetal loss
- Preoperative testing may be indicated to rule out cervical infection (gonorrhea/chlamydial infection).
- Ultrasonography is done before the procedure to confirm a normal intrauterine pregnancy.
- The procedure is done in an operating room and requires anesthesia (general or regional); the patient will need to have someone with her to drive her home after procedure.
- The procedure is usually done as an outpatient, same-day procedure.
- The patient will be placed on a fetal monitor before and after the procedure to document fetal viability
- After the procedure, acetaminophen (Tylenol) usually provides adequate pain control, if necessary.
- The patient may experience significant vaginal discharge for weeks after the procedure.
- The patient will need to be seen more frequently throughout the remainder of the pregnancy.
- Pelvic rest is often recommended; instruct the patient to limit physical activity for at least 1 week and to abstain from vaginal intercourse for at least 1 week and up to the entire pregnancy.

#### **PROCEDURE**

- 1. Obtain informed consent (see sample patient consent form online at www.expertconsult.com).
- 2. Document intrauterine viability.
- The patient is brought to the operating room and either a general or regional anesthetic is given. Local anesthesia or paracervical anesthesia is avoided because of concern for alteration in uterine blood flow.
- 4. Place the patient in the dorsal lithotomy position; prepare and drape in sterile fashion.
- 5. Drain the bladder (a Foley catheter is not necessary).
- 6. Place a weighted speculum in the posterior vagina.
- 7. Place a Deaver or right-angle retractor in the vagina to provide adequate exposure; have an assistant hold it carefully to avoid bladder trauma.
- 8. Using a ring forceps, grasp the anterior lip of the cervix and displace it superiorly.
- 9. Place a stitch at the 6 o'clock position in the mid-portion of the cervix equidistant from the ectocervix and the vaginal reflection (near the cervicovaginal junction). Place the suture through the mid-portion of the cervical stroma, being careful not to enter the cervical canal. Sutures that are too shallow may

- tear out when drawn tight. Be aware of the cervical vascularity. By starting at the 6 o'clock position instead of the 12 o'clock position, the patient may have decreased bladder irritation from the suture because the knot will rest in the posterior vagina. Direct the needle toward the 3 o'clock position within the cervical tissue.
- 10. Proceeding in a counterclockwise manner (clockwise if left-handed), pass the suture to the 3 o'clock position. Remove it from the cervix and then immediately loop it back into the cervix. Pass the stitch to the 12 o'clock position, again, within the tissue itself. Withdraw it and then reinsert in same area. Again pass the stitch to the 9 o'clock position, withdraw, and reinsert. Finally, pass the stitch to the starting position (6 o'clock) and withdraw the suture (see Fig. 133-1).
- Cinch down the suture like a pursestring without drawing too tightly and tie it, leaving ends long enough to grasp with ring forceps for removal.
- 12. Some surgeons prefer to place a second cerclage lower than the first, but no improvement in outcome has been documented and complications like membrane rupture or bladder perforation may be more frequent.
- 13. The patient then recovers while being placed on a fetal monitor to ensure fetal viability.
- 14. The patient is usually discharged after a period of adequate observation. Antibiotics are not recommended and tocolytic agents have no proven benefit.
- 15. Complete a postoperative note indicating the type of cerclage placed (McDonald), the suture type, the anesthesia, the location of the suture placement, and the number of knots placed. A diagram is helpful. Place a copy of the operative report in the pregnancy record.

#### REMOVAL

The cerclage is left in place until the 37th week of the pregnancy, at which time it can usually be removed easily in the office. The patient is placed in the usual examination position with the speculum placed. The knot is then grasped with the pickups (e.g., a Russian), the knot is elevated, and the Metzenbaum scissors are used to cut the cerclage stitch, which is then easily removed. If, however, difficulty arises when attempting to remove the stitch, the clinician should not hesitate to proceed to the operating room. If preterm labor is encountered later in the pregnancy and tocolysis is not successful, the cerclage should be removed at that time to avoid damage to the cervix.

#### SAMPLE OPERATIVE REPORT

Procedure:	McDonald cervical cerclage
Preop diagnosis:	Cervical insufficiency at wks
	gestation
Postop diagnosis:	Same
Surgeon:	
Anesthesiologist:	
Estimated blood loss:	cc
Specimen:	None
Drains:	None
Complications:	None
Disposition:	To Labor and Delivery for observation
History and Indicatio	ns
Ms.	is a year old
G P	at weeks' gestation with a
viable fetus. She had	prior 2nd trimester pregnancy losses
	ve of cervical insufficiency. The plan was to
, 00	ge at 14 weeks. The patient was informed of
	of the procedure and signed the appropriate
	of the procedure and signed the appropriate
consent form.	

#### **Procedure**

Fetal heart tones were documented and the patient was seen by me and the anesthesiologist. The patient was then taken to the operating room, room no. \_\_\_\_\_\_, where she received a spinal anesthetic by Dr. \_\_\_\_\_. She was then placed in the dorsal lithotomy position. After verifying the adequacy of the spinal anesthetic, the patient was prepped and draped in the usual manner and her bladder was drained of \_\_\_\_\_\_ cc of urine.

A weighted speculum was placed in the vagina and the anterior lip of the cervix was gently grasped. No membranes protruded through the external cervical os.

A no. 5 Mersilene tape suture was placed at the 6 o'clock position at the level of the internal os with the suture exiting at the 3 o'clock position, reinserted in this same area, exiting at the 12 o'clock position. The suture was reinserted at the 12 o'clock position and removed at the 9 o'clock position, reinserted in this same area, exiting at the 6 o'clock position. The suture was tied with three knots at the 6 o'clock position. No significant bleeding was noted.

The weighted speculum and ring forceps were removed and the patient transferred from the operating table to a bed and then transported to Labor and Delivery in the care of the anesthesiologist, Dr. , in stable condition.

Signature, date, and time: \_

#### **COMMON ERROR**

Placing a suture too shallowly so that it pulls out when tightened is a common error.

#### **COMPLICATIONS**

- Rupture of membranes (incidence may be up to 65% within 2 weeks)
- Chorioamnionitis (may occur in up to 30% of cases)
- Uterine rupture
- Maternal septicemia
- Pregnancy loss
- Scarring of the cervix, which may cause cervical and potential uterine injury during labor
- Suture may migrate; may need to replace cerclage if still early in pregnancy (<24 weeks)</li>
- Significant vaginal discharge from the foreign body reaction of the cervical suture
- Increased frequency of contractions

#### POSTPROCEDURE PATIENT CARE

- Monitor the patient until adequately recovered from anesthesia and patient is able to ambulate and void.
- Fetal viability must be documented before discharge.
- Acetaminophen should provide any necessary pain relief.
- Patient discharge instructions should include the following:
  - Vaginal discharge after the procedure is normal and may continue for weeks.
  - Call office with any leakage of fluid from the vagina, fever, severe cramping or pain.
  - Pelvic rest and limited physical activity for at least 1 week if procedure was elective; if procedure was emergent, pelvic rest and limited activity throughout remainder of pregnancy.
- See patient frequently (weekly or biweekly) for cervical checks.

#### POSTPROCEDURE PATIENT EDUCATION

The patient should avoid vaginal intercourse and limit physical activity for the first week after the procedure. Consider no intercourse and no heavy physical activity until after delivery.

- Vaginal discharge may be normal for weeks after this procedure. The patient should contact her physician if she experiences severe cramping, fever, or any vaginal bleeding.
- Acetaminophen is helpful for any pain or discomfort after this procedure.
- Monitor the patient closely with checks every 1 to 2 weeks.
- Advise that a second stitch may be needed if the first stitch does not remain tightly secured.
- The stitch will be removed at around 37 weeks' gestation, and this is usually done in the office.

Be aware that there is little evidence to support these recommendations, and they may be modified to fit the individual situation. Any emergently placed cerclage is monitored more closely.

#### **CPT/BILLING CODES**

59320 Cerclage

59871 Removal of cerclage suture under anesthesia (other than local)

No CPT code exists for removal of a cerclage without anesthesia.

#### **ICD-9-CM DIAGNOSTIC CODES**

622.5 Incompetent cervix

654.53 Incompetent cervix in pregnancy

761.0 Incompetent cervix in pregnancy affecting fetus or newborn

## CERVICAL CONIZATION

Lydia A. Watson

In most cases, proper evaluation of abnormal Pap smears and cervical lesions includes colposcopy, multiple-punch biopsy sampling, and endocervical curettage. However, conization of the cervix plays an important role in both the diagnosis and the management of abnormalities of the cervix. Cold-knife conization (CKC) is considered the gold standard by which all other outpatient techniques are critiqued. "Cold knife" refers to a surgical blade versus the old "hot-wire" cone, or the loop procedure.

Conization of the cervix consists of the removal of a cone-shaped wedge of tissue from the cervix uteri. To be considered an adequate specimen, the tissue removed must include the entire transformation zone with the squamocolumnar junction and the entire lesion surrounded by uninvolved margins. The large loop electrical excision procedure is described in Chapter 149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia. A review of Chapter 137, Colposcopic Examination, and Chapter 138, Cryotherapy of the Cervix, is also recommended.

#### **INDICATIONS**

A conization may be indicated for diagnosis or treatment, or both. Usually any conization method can be used interchangeably, although using a knife blade causes less tissue artifact (pathologic distortion) than other methods and may allow a better histologic examination.

#### For Diagnosis

- Inadequate colposcopic evaluation of the cervix
  - The lesion is not seen on colposcopic examination, but Pap smear is significantly abnormal
  - Incomplete visualization of a lesion that extends into the endocervical canal (ECC) on colposcopic examination
  - Inadequate visualization of entire transformation zone, including the squamocolumnar junction (e.g., goes into the os, where it cannot be evaluated)
- Positive endocervical curettings (i.e., dysplasia or cancer)
- Inconsistencies between cytologic findings, histologic diagnoses, and colposcopic impression (e.g., a Pap smear that is at least two stages worse than colposcopic biopsy)
- Inability of colposcopic examination to exclude invasive cancer

#### For Therapy

- Cytology or biopsy specimen suggests microinvasive carcinoma
  of the cervix (clinician must rule out frank invasion to define
  the proper treatment; in this case, procedure may also be
  therapeutic)
- High-grade dysplasia (i.e., moderate or severe dysplasia by biopsy) greater than 2 cm or in more than two quadrants
- Cervical cryotherapy is contraindicated (see Chapter 138, Cryotherapy of the Cervix)
  - Lesion too large for cryotip

- Markedly irregular surface of cervix with crevices that cryotherapy will not reach
- Glandular involvement on biopsy (relative)
- Lesion extends more than 5 mm into the os
- Noncompliance (e.g., patient unlikely to be compliant with follow-up after cryotherapy and during attempts to monitor lesser cervical intraepithelial neoplasia without treatment)
- Correction of cervical stenosis (although the os is more likely to be opened using a shallow LEEP than a CKC)

#### **CONTRAINDICATIONS**

#### Absolute

- Known frank invasive carcinoma of the cervix or endocervix ("Carcinoma in situ" is not a cancer, but rather a severe dysplasia.
   With microinvasive cancer, a conization procedure must be performed to rule out frank invasion.)
- Patient with contraindications to general or regional anesthesia
- Unstable medical conditions (rarely is conization an emergency)

#### Relative

- Unstable bleeding disorders
- Inflammatory cervicitis (causes increased bleeding)
- Heavy menses at time of surgery (makes the procedure more difficult)
- Pregnancy

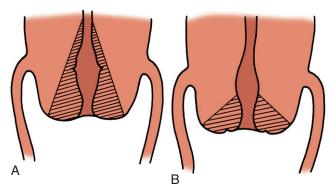

**NOTE:** Although pregnancy is not an absolute contraindication to conization, only a well-trained physician capable of managing complications should perform the procedure on a pregnant patient (see the "Complications" section).

#### PREPROCEDURE PATIENT EDUCATION

- The procedure and potential complications should be explained to the patient, and written informed consent should be obtained. (See the patient education handout titled "Cold-Knife Conization of the Cervix [Cone Biopsy]" available online at www.expertconsult.com.)
- The need for general, local, or regional anesthesia should be explained.
- All options for treatment and evaluation should be explained.

#### **EQUIPMENT**

- Povidone-iodine
- Colposcope with green filter
- Acetic acid and full-strength Lugol's solution
- Vasopressin 20 U in 20 mL of normal saline for infiltration of the cervix
- · Long scalpel handle with no. 11 blade

**Figure 134-1** Variation in size and shape of cervical tissue removed during conization. **A,** For large ectocervical lesion. **B,** For canal lesions.

- Long, fine-tooth forceps
- Kevorkian endocervical curette
- Electrocautery unit
- 0-chromic or 0-Vicryl suture (or Surgicel, Gelfoam, or Avitene) for hemostasis; long needle holders
- Large Graves speculum
- Uterine sound

#### **PROCEDURE**

- 1. Special considerations: Most lesions are found on the ectocervix in premenopausal women, so the cone should have a broad base and the top should have a wide angle (Fig. 134-1A). In postmenopausal women, the specimen will be long and narrow, with an acute angle at the cone top. The squamocolumnar junction in these patients has generally moved inside the ECC, and lesions are more likely to be endocervical. The transformation zone in older women is usually quite small (Fig. 134-1B).
- 2. Administer general, local (intrastromal), or regional anesthesia to the patient, and obtain adequate exposure of the cervix. The bladder should be drained.
- Apply full-strength Lugol's solution to the cervix to aid in determining the width of the cone base. All areas that do not stain will be removed. Alternatively, perform colposcopy using acetic acid and the green filter to demarcate the lesion and the transformation zone.
- 4. Obtain hemostasis by circumferentially infiltrating the cervical stroma with a solution of 20 U of vasopressin diluted in 20 mL of normal saline (Fig. 134-2).

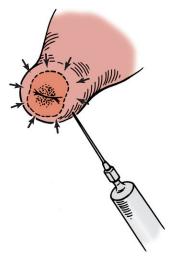

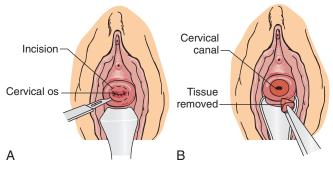

Figure 134-2 Intracervical injection.

**Figure 134-3** Conization technique (see text for details). **A,** Incision. **B.** Removal of tissue.

NOTE: Hemostatic retention sutures are no longer routinely used.

- 5. Gently sound the uterine canal to determine position and size of the uterus.
- 6. Incise the cervix in a circular fashion, making the incision outside of the Lugol's-negative or acetowhite area. Begin at the 6 o'clock position. This will prevent the blood that runs down from obscuring the incision line (Fig. 134-3A). Angle the blade centrally to the width and depth desired.
- 7. Use a fine-tooth forceps to elevate the cone away from the underlying bed. Avoid damaging the cervical epithelium (Fig. 134-3B)
- 8. Mark the 12 o'clock position of the specimen for the pathologist with a single suture placed into the cervical stroma. Consider measuring the specimen because it may shrink before it is measured by the pathologist.
- 9. Curette the remainder of the ECC with a small curette to rule out disease above the upper margins of the cone.
- 10. Perform a dilation and curettage, if indicated, at this time.
- 11. Obtain hemostasis with superficial electrocoagulation by using a ball electrode or individual suture ligatures to control bleeding. The cone site may also be packed with an absorbable gelatin sponge (e.g., Gelfoam) or similar hemostatic material. Most apply Monsel's solution to the base of the excision after coagulation.
- 12. Place the cone specimen in fixative to send for pathologic interpretation.

#### **COMPLICATIONS**

Complications for the nonpregnant patient include the following (overall complication rate 10%):

- Pain and cramping (generally minimal).
- Immediate or delayed hemorrhage. (Eschar sloughs in 7 to 10 days. Delayed hemorrhage can occur at this time; some spotting is to be expected for 10 to 14 days.) If bleeding is excessive at the time of surgery, inject 1 mL of 2% lidocaine with epinephrine into each bleeding spot. This will usually slow bleeding enough to allow electrocoagulation. Alternatively, and rarely, a "figure-of-8" stitch may need to be placed over the bleeding vessel.
- Cervical stenosis (<3 mm) that prevents menses or obtaining a good endocervical Pap smear.
- Uterine perforation.
- Pelvic cellulitis (very rare) or cervicitis.
- Damage to the bladder or rectum. (This is usually seen in cases of significant vaginal atrophy with shallow vaginal fornices.)
- Cervical incompetence.
- Infertility caused by loss of mucus-producing endocervical glands.
- Anesthetic complications.

- Positive margins or positive ECC. (If ectocervical margins show only dysplasia, the patient should be followed closely but a repeat cone is not indicated. Usually the lesion will resolve during the inflammatory healing process. A repeat cone may be indicated in older patients who are at a high risk and do not desire pregnancy, those who have had pelvic irradiation, or in whom both the margins and ECC are positive. If the ECC above the excisional site is positive with a high-grade lesion, repeat conization should be considered.)
- Missing the lesion (rare).

In addition to the complications mentioned for the nonpregnant patient, complications for the pregnant patient include the following:

- Fetal loss rate of 10% (secondary to rupture of the membranes, premature labor, and excessive hemorrhaging).
- Postoperative hemorrhage rate of 30%.

# POSTPROCEDURE MANAGEMENT

- A follow-up appointment should be scheduled for 4 to 6 weeks.
- The patient should be instructed to avoid intercourse, douching, and tampon use until follow-up examination confirms healing.
- The patient should be asked to notify the clinician of elevated temperature, excessive vaginal bleeding, or purulent discharge.
- The first follow-up Pap smear should be scheduled in 3 to 4 months if all margins are clear.

# **CPT/BILLING CODES**

- 57520 Conization, with or without fulguration, with or without dilation and curettage (D&C), with or without repair, cold knife or laser
- 57522 Conization, loop electrode
- 57505 Endocervical curettage (not done as part of D&C)
- 99070 Surgical tray

# **ICD-9-CM DIAGNOSTIC CODES**

- 078.11 Condyloma
- 079.4 Human papillomavirus infection
- 180.9 Cervical neoplasm, malignant (excludes carcinoma in situ)

- 219.0 Benign neoplasm, cervix
- 233.1 Carcinoma in situ, cervix (includes CIN III, severe dysplasia of cervix)
- 622.0 Cervical erosion or ulcer
- 622.1x Dysplasia of cervix (5th digit required, 0 unspecified, 1 mild [CIN I], 2 moderate [CIN II])
- 622.2 Cervical leukoplakia
- 622.4 Cervical stenosis
- 622.7 Cervical polyp

# **CERVICAL POLYPS**

Beth A. Choby

Cervical polyps affect 4% of women. Although their etiology is poorly understood, polyps are associated with obstructed cervical blood vessels, pregnancy, chronic inflammation, and an abnormal response to increased estrogen. Women with diabetes or recurrent vaginitis may be at increased risk. Most cervical polyps are benign, although 1% of lesions undergo malignant transformation. Because of this risk, polyps are generally removed and histologically examined to rule out precancerous change.

The incidence of cervical polyps increases with age. Cervical polyps are rarely seen in girls who have not reached menarche. Polyps are fairly common in parous women in their 20s. Diagnosis is often made during a routine speculum examination. Multiparous women 30 to 50 years of age and perimenopausal women are most often affected. The influence of hormone therapy on the progression of cervical polyps is not well defined. Postmenopausal cervical polyps are often associated with endometrial polyps. Women taking tamoxifen who have a cervical polyp are significantly more likely to have concomitant endometrial polyps. Evaluation with hysteroscopy is indicated in this situation.

Most cervical polyps are asymptomatic and found by chance during routine gynecologic examination. When present, symptoms are usually vague and include vaginal spotting or bleeding after exercise, douching, or intercourse. Vascular congestion and edema cause ulceration of the polyp tip and postcoital bleeding. Larger polyps are associated with intermenstrual spotting. Defecation or straining can cause bleeding. Abnormal menses or nonpurulent vaginal discharge is sometimes noted. When cervical polyps cause postmenopausal vaginal bleeding, further work-up to exclude malignancy is mandatory.

Cervical polyps range in size from a few millimeters to several centimeters. Polyps on longer pedicles (stalks) sometimes protrude from the vaginal orifice. Large endocervical polyps cause cervical dilation and pain.

The differential diagnosis for cervical polyps is given in Box 135-1. Because cervical polyps often coexist with endometrial polyps, hysteroscopy has been suggested as the first-line therapy in the management of cervical polyps. Older recommendations include performing a suction dilation and curettage with all cervical polypectomies. Current literature fails to support either intervention as substantially improving outcomes compared with routine simple polyp removal. In low-risk, asymptomatic women, most physicians still proceed with in-office cervical polypectomy.

## **ANATOMY**

Cervical polyps are pedunculated tumors arising from endocervical or ectocervical tissue. *Endocervical* polyps originate within the endocervical canal, are most common in premenopausal women, and can prolapse through the cervix (Fig. 135-1). *Ectocervical* polyps more often affect postmenopausal women (Fig. 135-2). Polyps are bright

red to pink and appear spongy. Polyps are most often solitary, although multiple polyps are sometimes encountered.

Endometrial polyps are sometimes confused as being of cervical origin. Endometrial polyps can protrude through the endocervical canal. Management of endometrial polyps is more complicated because the polyp's blood supply is usually more extensive and the attachment is much higher up (Fig. 135-3).

Some lesions can mimic cervical polyps and be benign (Fig. 135-4), whereas malignant conditions such as adenocarcinoma can also masquerade as a polyp. Histologic study is often the only way to be certain of the true nature.

#### INDICATIONS FOR REMOVAL

- Asymptomatic cervical polyps found on routine gynecologic examination
- Cervical polyps associated with pain, bleeding, or other symptoms

#### CONTRAINDICATIONS

#### **Absolute**

- Patient unwilling/unable to consent to procedure
- Patient unwilling/unable to cooperate with vaginal examination

#### Relative

- Endometrial polyps or cervical polyps with a dense, thick pedicle/ blood supply
- Polyps larger than several centimeters (may be better removed in a surgical suite)
- Pregnancy
- Blood dyscrasias
- High likelihood of multiple polyps (consider hysteroscopy)

# Box 135-1. Differential Diagnosis of Cervical Lesions

Cervical malignancy

Cervical polyp

Condyloma

Endometrial polyp

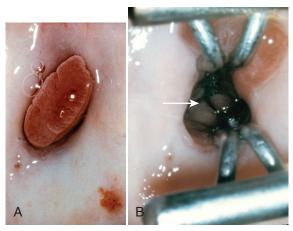

Nabothian cyst

Prolapsed myoma

Retained products of conception

Sarcoma

Squamous papilloma

**Figure 135-1 A,** Endocervical polyp. **B,** Identification of polyp base (*arrow*) using an endocervical speculum. (Courtesy of Duane Townsend, MD.)

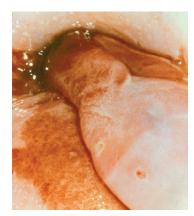

Figure 135-3 Dysplastic endometrial polyp. Stalk originates in endometrial cavity. (Courtesy of Duane Townsend, MD.)

# **EQUIPMENT AND SUPPLIES**

- Nonsterile gloves
- Vaginal speculum
- Colposcope (optional)
- Ring forceps
- Cervical biopsy forceps (may not be needed)
- Endocervical curette (Kevorkian)
- Pathology specimen containers
- Silver nitrate sticks
- Topical anesthetic (lidocaine jelly or benzocaine solution), though this is usually not needed
- Kogan's endocervical speculum

#### **PRECAUTIONS**

- Identify the base of the polyp stalk to exclude an endometrial polyp. Endometrial polyps are often larger with more vascular stalks. Suspect an endometrial polyp if the stalk extends into the cervix or remains visible after polypectomy. Endometrial polypectomy is most often done by hysteroscopy.
- Cervical polyps have increased vascularity during pregnancy. Asymptomatic polyps that do not change in size or appearance may be observed and removed after delivery. If bleeding necessitates removal during pregnancy, electrocautery or loop electrosurgical excision procedure is sometimes required.

 Remove large cervical polyps in an outpatient surgical suite. Hysteroscopy is useful for confirming the size and origin of polyps found deeper inside the endocervical canal.

# PREPROCEDURE PATIENT EDUCATION AND FORMS

Naproxen (500 mg) or a similar nonsteroidal anti-inflammatory drug is given orally 1 hour before the procedure. The procedure should not be scheduled during menses. Discuss risks and benefits of the procedure with the patient and obtain informed consent. Please see the consent form available online at www.expertconsult.com.

# **PROCEDURE**

- 1. Don nonsterile gloves and insert a vaginal speculum. If a recent Pap examination has not been performed, it can be completed before the procedure.
- 2. Visualize the polyp. The use of a colposcope may improve visualization.
- Gently manipulate the cervical os using ring forceps to identify the polyp base. Use a Kogan's endocervical speculum if the stalk extends into the endocervical canal.
- 4. Determine whether the polyp is cervical or endometrial in origin.
- 5. Remove the polyp using one of the following methods:
  - Cut through the tissue at the base of the polyp using cervical biopsy forceps.

**Figure 135-2** Ectocervical polyp. Stalk is attached to the ectocervix. Note the intrauterine device strings. (Courtesy of The Medical Procedures Center PC, Midland, Mich.)

**Figure 135-4** Suspected cervical polyp, which is actually a large nabothian cyst. (Courtesy of The Medical Procedures Center PC, Midland, Mich.)

- Grasp the polyp with the ring forceps and twist the forceps around the stalk until it comes off. Patients may complain of mild discomfort.
- If the polyp is small, scrape it off in its entirety using a sharp curette.
- 6. Place the cervical polyp and stalk into a specimen container with formalin.
- 7. Perform an endocervical curettage using a Kevorkian curette (see Chapter 137, Colposcopic Examination). Although this step is optional, it ensures that all of the abnormal tissue has been removed. Place the tissue in a separate specimen container from the cervical polyp.
- 8. Control bleeding using silver nitrate, Monsel's solution, or cautery. Bleeding is usually minimal. Silver nitrate also destroys residual polyp tissue and minimizes the chance of recurrence.

#### SAMPLE OPERATIVE REPORT

See the sample operative report online at www.expertconsult.com.

#### **COMMON ERRORS**

 Failure to remove the polyp, stalk, and base entirely. The use of a colposcope to identify the origin of the polyp before excision may facilitate complete removal.

When multiple polyps are present, it is best to thoroughly curette the endocervical canal. If the patient is postmenopausal, has irregular bleeding, or takes tamoxifen, a dilation and curettage or hysteroscopy may be a better option.

 Misidentification of a prolapsed endometrial polyp as a cervical polyp.

#### COMPLICATIONS

- Postprocedure bleeding or spotting
- Postprocedure pain
- Recurrence

# POSTPROCEDURE MANAGEMENT

- Monitor the patient for vasovagal reactions.
- Provide the patient with a sanitary pad.
- Advise the patient to take a nonsteroidal anti-inflammatory drug for 24 hours as needed for abdominal cramping.

### POSTPROCEDURE PATIENT EDUCATION

Patients should avoid tampon use, douching, or sexual intercourse for 1 week after cervical polypectomy. Active vaginal bleeding warrants timely reevaluation. Patients are followed up at 6 to 8 weeks. Because polyps are generally benign and no further treatment usually needed, routine gynecologic surveillance is appropriate.

# **PATIENT EDUCATION GUIDES**

See patient education and consent forms and sample operative report available online at www.expertconsult.com.

# **CPT/BILLING CODES**

There is no separate CPT code for cervical polyp removal.

- 57500 Biopsy of the cervix, single or multiple, or local excision of lesion, with or without fulguration
- 57505 Endocervical curettage (not performed as part of dilation and curettage)

#### **ICD-9-CM DIAGNOSTIC CODES**

- 078.11 Condyloma acuminatum
- 219.0 Benign neoplasm of the cervix (adenomatous polyp of the
- 236.0 Neoplasm of uncertain behavior: uterus
- 621.0 Polyp endometrium/uterus NOS
- 622.7 Polyp of cervix NOS
- 625.9 Unspecified symptoms associated with female genital organs
- 626.6 Metrorrhagia. Bleeding unrelated to menstrual cycle; irregular intermenstrual bleeding
- 627.1 Postmenopausal bleeding

# CERVICAL STENOSIS AND CERVICAL DILATION

Linda Prine

Cervical stenosis is a stricture or narrowing of the cervix. It is diagnosed by the inability to pass a 2-mm dilator into the uterus. Cervical stenosis can be either *congenital* or *acquired*. Acquired stenosis can result from postoperative scarring (from conization, whether it be cold knife, large loop electrosurgery, or laser; cautery; or cryotherapy of the cervix), cancer (endometrial or endocervical), radiation complications, infections, or atrophy from lack of estrogen (most common). In acquired cases the external os is most frequently affected (Fig. 136-1). In *congenital cases*, seen most often in nulliparous cervices, the stenosis is usually at the internal os.

Narrowing of the cervical canal can impede menstrual flow, causing intrauterine pressure during menses. Premenopausal women with cervical stenosis may have pelvic pain, dysmenorrhea, amenorrhea, infertility, or abnormal bleeding. In some cases retrograde menstrual flow may occur, causing endometriosis. Women may have a soft, slightly tender midpelvic mass as a result of hematometra. Postmenopausal women may have pyometra, which is highly suspect for endometrial carcinoma.

Ultrasonography can assess canal anatomy while evaluating the patient for hematometra and a pyometra. Most often, cervical stenosis is discovered when the physician is attempting to enter the uterus for a Pap smear, hysteroscopy, intrauterine device (IUD) insertion, endometrial biopsy, uterine aspiration for elective or spontaneous abortion, or placement of Essure devices.

### **CERVICAL DILATION**

Treatment of cervical stenosis consists of dilation by using (1) progressive metal or plastic dilators, (2) osmotic tents, or (3) prostaglandin analogs. Laminaria tents are made from the stems of seaweed, usually Laminaria japonica, that is dried and made into sticks. Self-expanding cervical dilators (Dilateria, Lamicel) that resemble laminaria tents can also be used. Once the tents are placed into the endocervical canal, they rehydrate and expand, thereby causing dilation of the cervical canal (Figs. 136-2 and 136-3). Laminaria tents should not be used if pyometra is present or infection is suspected. The os and canal must be patent enough to admit the tents, which are available in several diameters. Some mechanical dilation may be necessary to allow their placement. Another option for the treatment of external os stenosis is the use of the carbon dioxide laser or a small radiofrequency loop excision. The latter two methods can remove a stricture that is readily visible externally.

Recently, clinicians have come to depend on the administration of  $\it{misoprostol}$  for softening and dilating the cervix. Misoprostol is most effective on the pregnant uterus, and very small doses are used to soften the cervix for labor. Documentation of efficacy is best in the pregnant uterus. In nonpregnant uteri, efficacy has been shown clearly in women of reproductive age. Studies of misoprostol use on postmenopausal women are conflicting regarding its effectiveness. In nonpregnant uteri or in the first trimester, two to four 200- $\mu g$  tablets administered vaginally, buccally, or sublingually 1 to 2 hours before the procedure is usually effective.

The majority of dilations can be performed in the office. For extremely anxious patients or if pain cannot be controlled easily, the procedure may need to be performed in the operating room.

#### **INDICATIONS**

- Symptomatic stenosis (e.g., dysmenorrhea)
- Inability to obtain adequate Pap smears
- IUD insertion
- To perform an indicated endocervical curettage or dilation and curettage
- To perform an aspiration abortion
- If needed for hysterosalpingogram
- Before hysteroscopy
- Before endometrial ablation techniques
- To perform an endometrial biopsy
- To insert Essure devices for mechanical tubal occlusion

# **CONTRAINDICATIONS**

# **Absolute**

The procedure is absolutely contraindicated in a patient who is trying to become pregnant.

# Relative

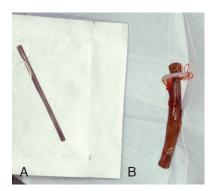

- · Laminaria tents are not to be used in cases of pyometra
- Pelvic inflammatory disease; vaginal or cervical infections (treat before dilation)

# **EQUIPMENT**

- Table that allows the patient to be placed in the lithotomy position
- Needle extender or long spinal needle to provide local anesthesia, if needed (see Chapter 149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia)
- 5 mL 1% lidocaine
- Adequate light source
- Appropriately sized vaginal speculum
- Nonsterile gloves; use sterile gloves if a procedure entering the uterus is to be performed
- · Ring forceps
- Uterine sound—plastic, malleable preferred
- Denniston plastic dilators (1 to 8 mm; Fig. 136-4) or metal dilators (1 to 6 mm) and/or osmotic tent (various sizes; see Fig. 136-2)
- OS Finder or os locator or small silver probe (like a tear duct probe)
- Cervical single-tooth tenaculum
- Paracervical block kit with 10 mL 1% lidocaine in a 10-mL syringe with a 6-inch, 20-gauge needle; may be helpful if dilation

**Figure 136-1** External os stenosis after loop electrosurgical excision procedure.

**Figure 136-2 A,** Laminaria before insertion. **B,** Swollen laminaria after removal.

Figure 136-3 Close-up of laminaria in Figure 136-2A.

Figure 136-4 Denniston plastic dilators, 5 mm to 14 mm sizes.

Figure 136-5 OS Finder.

of more than 4 to 6 mm is done (see Chapter 173, Paracervical Block)

- 4 × 4 gauze; povidone–iodine (Betadine) solution
- Ultrasonography machine with abdominal probe if needed for guidance (optional)

# PREPROCEDURE PATIENT EDUCATION

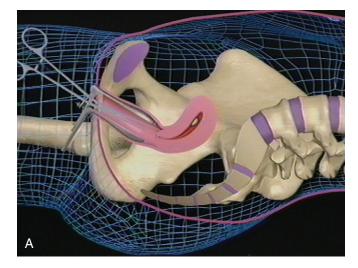

- Obtain informed consent from the patient. (See the patient consent form available online at www.expertconsult.com.)
- The patient can insert 400 to 800  $\mu g$  of misoprostol at home before the procedure, or the clinician can insert it at the time of the procedure when the stenosis is discovered.
- Generally 800 mg of ibuprofen 1 hour before the procedure helps with pain management. Consider diazepam 10 mg by mouth for the anxious patient.
- If further sedation is needed, see Chapter 2, Procedural Sedation and Analgesia.

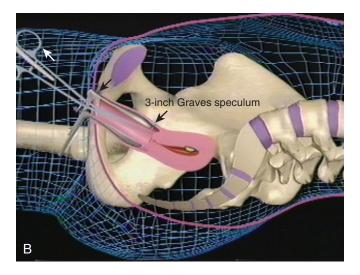

#### **PROCEDURE**

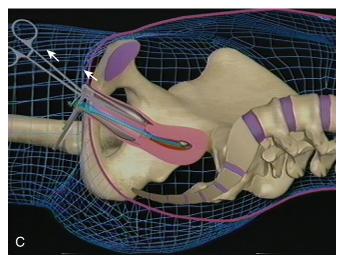

- 1. Place the patient in the lithotomy position.
- 2. Perform a pelvic examination to evaluate the uterine size and position.
- 3. Prepare the cervix and vagina with povidone–iodine (or diluted chlorhexidine if the patient is allergic to povidone–iodine).
- 4. Try to cannulate the cervical canal with a small silver probe, the 2-mm dilator, or the OS Finder or os locator (Fig. 136-5). If the patient becomes uncomfortable, administer 5 mL of a local anesthetic *submucosally* at the 12, 3, 6, and 9 o'clock positions on the cervix (see Chapter 149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia), or use a paracervical block with 5 mL lidocaine at the 4 and 8 o'clock positions (see Chapter 173, Paracervical Block). Aspirate for blood before injecting to ensure that the needle is

**Figure 136-6** Single-tooth tenaculum placed posteriorly (*arrow*) on the cervix.

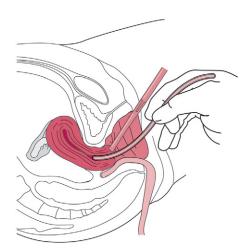

**Figure 136-7** Applying traction to the cervix is often the solution to the problem of uteri with extremes of anatomic flexion. **A**, A tenaculum has been applied to the cervix of an anteroflexed uterus. **B**, By applying outward traction (*arrows*) on the tenaculum, the uterus is straightened. **C**, Dilators can now be inserted. Additional pressure on the speculum against the perineum is sometimes needed for the acutely ante-flexed uterus in order to create a straightened passageway.

- not in a blood vessel. The use of a local injection into the cervix may obviate the need for the more complicated and uncomfortable paracervical block.
- 5. If the cervix is too mobile, place a tenaculum at the 12 o'clock or 6 o'clock position and use it to apply traction on the cervix while dilating it (Fig. 136-6). The straightening action of placing traction on the cervix (Fig. 136-7) is often the solution to the problem of uteri with extremes of anatomic flexion. Use progressively larger dilators and proceed slowly.
- 6. Once the external os is entered, the most difficult part of the procedure is passing through the internal os. If the sound/dilator does not pass readily, apply the tenaculum if not already done. The OS Finder or os locator usually enters the lumen without creating a false passage. It often takes firm, steady pressure on dilators to penetrate the internal os. To avoid perforation, the plastic Denniston dilators are strongly recommended. (This step causes significant anxiety in the clinician!) The clinician should be able to feel the smooth contour of the cervical canal. A rough surface as the dilator advances is a strong indicator that a false passage is being created. (If the roughness is felt, this would be a good time to confirm orientation with ultrasonography, if not already in use.) As the tenaculum is pulled outward, the dilator is pushed forward until a "give" is felt. Insert the dilator finder just through the internal os.
- 7. Gradually insert larger dilators until the degree of dilation needed for the particular procedure is attained.
- 8. A plastic, malleable or metal uterine sound can be inserted to determine the size of the uterine cavity, if needed. If a metal sound is used, bend it to conform to the position of the uterus as determined on the pelvis (anteverted or retroverted). The sound should pass easily before resistance is felt. For the normal-size uterus, this should be no more than 10 cm (possibly 12 cm). If the sound goes beyond this, suspect perforation unless the clinical examination or ultrasonography suggested a large uterus. If a perforation occurs, stop further efforts. (See later discussion.)
- Dilation to 4 to 6 mm is sufficient for most non-pregnancyrelated procedures and is usually readily accomplished in the office. When inserting the dilator, rest your fourth and fifth fingers on the perineum and buttocks to prevent uncontrolled movements of the dilator (Fig. 136-8).
- 10. Perform the procedure indicated.

**Figure 136-8** Cervical dilation using a Hegar dilator. During the procedure, the fourth and fifth fingers rest against the perineal area in order to prevent uncontrolled movements of the dilator, which can lead to uterine perforation. A weighted speculum is in the posterior vagina. The tenaculum is applied to the anterior lip of the cervix. (Adapted from Cunningham FG, MacDonald PC, Gant NF, et al. [eds]: Williams Obstetrics, 20th ed. Stamford, Conn, Appleton & Lange, 1997.)

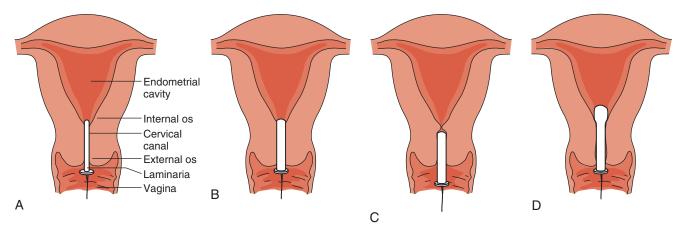

Figure 136-9 Insertion of a laminaria tent. **A,** The laminaria tent immediately after placement. Note that the upper end is just through the internal os. It is difficult to determine this "optimal" position, and it is not possible to obtain it with internal os stenosis. **B,** The laminaria tent 24 hours later. **C,** The laminaria tent not placed far enough to dilate the internal os. **D,** The laminaria tent inserted too far, making it difficult to remove. (Adapted from Cunningham FG, MacDonald PC, Gant NF, et al. [eds]: Williams Obstetrics, 20th ed. Stamford, Conn, Appleton & Lange, 1997.)

# LAMINARIA TENT PLACEMENT

- For laminaria tents to be used, the external os must be patent. Subsequently, they are used either for internal os stenosis or for a gradual dilation of the canal for larger procedures. They come in various sizes, and more than one may be inserted for greater dilation if needed.
- 2. Prepare the patient and cervix as described previously.
- 3. Sound the endocervix if possible.
- 4. Grasp the cervix with the tenaculum, if necessary, and use it to apply traction on the cervix (see Fig. 136-6).
- 5. Hold the *string end* of the laminaria with ring forceps and insert it into the os, ensuring that the laminaria tent does not extend into the uterine cavity. Use the largest laminaria tent that will fit into the os. Sometimes, this may be quite small. If unable to insert the laminaria tent, you may have to dilate the os further before its insertion (Figs. 136-9 and 136-10).
- Laminaria are quite long and usually protrude out of the cervix for several millimeters.
- 7. Cover the cervix and the inserted laminaria with a sterile 4 × 4 gauze that has been dipped into *dilute* povidone–iodine solution, and tuck the edges in the fornices. Then place several dry 4 × 4 gauzes over the first one to hold the laminaria tent in place (Fig. 136-11).
- 8. Remove the speculum while holding the gauze in place with the ring forceps.
- 9. To prevent infection, the laminaria tent should be removed within 24 hours by grasping it with a ring forceps, rotating it

- 360 degrees, and pulling it out. Lesser procedures may only require 8 to 12 hours. Often the laminaria is inserted at the end of the day and removed the next morning. Alternatively, the patient can be the first one seen during the morning, with the laminaria removed when she is seen again as the last patient of the day. It may be necessary to replace the initial smaller laminaria with a larger one if the dilation is not adequate on removal.
- Dilation can cause significant cramping, and ibuprofen 600 mg every 6 hours is advised.

## **COMMON ERRORS**

- The most common error is failure to straighten the uterus. This occurs by not placing sufficient traction on the tenaculum or by using a speculum with long blades, trapping a flexed uterus in its flexed position. Failure to make this adjustment can result in uterine perforation, the most common complication of a difficult dilation.
- The laminaria may fail to dilate the canal because it has not been inserted far enough. Sounding the canal and marking the laminaria will aid in knowing when it has been inserted far enough (see Fig. 136-9C).
- The laminaria can be inserted too far, making it difficult to remove because of a bulbous swelling inside the uterine cavity (see Fig. 136-9D).

**Figure 136-10** Laminaria tent has been inserted. It is difficult to appreciate that the tent actually protrudes 2 mm outside the cervix.

**Figure 136-11** Laminaria held in place with  $4 \times 4$  gauze inserted in the vagina. Patients tolerate this surprisingly well.

# **COMPLICATIONS**

- Pain
- Hemorrhage
- Infection (especially if the laminaria tent is left in over 24 hours)
- Anaphylaxis or allergic reaction to the laminaria tent or misoprostol (rare)
- Inability to dilate the os
- Laminaria tents can break or separate on removal, making retrieval of the pieces difficult
- Inability to remove the laminaria because of an excessively deep placement

Many physicians are fearful of a *perforation*, but it is generally uneventful unless it is not recognized. The perforation can be complicated if further procedures are attempted and the instruments are introduced beyond the uterine cavity. If perforation is suspected, no further instrumentation should be done. Explain to the patient what is suspected. After 30 minutes of observation she can go home if vital signs are stable and there is no pain. She should report any fever, pain, or excessive bleeding. A follow-up visit or phone call within 24 hours is advisable. Repeat cannulation or dilation can be attempted after 6 to 8 weeks.

#### POSTPROCEDURE PATIENT EDUCATION

See also Chapter 141, Dilation and Curettage.

- If a laminaria tent is placed, the patient should be instructed to return within 24 hours for removal of the laminaria tent. Eight to 12 hours is often adequate.
- The patient should not engage in sexual intercourse while the laminaria is in place.
- If dilation was performed for cervical stenosis causing hematometra or pyometra, or after an excisional procedure, the patient should be instructed to return in 4 to 6 weeks for repeat examination and possible repeat dilation.
- The patient should return or call for fever, abdominal or pelvic pain, purulent vaginal discharge, or bleeding.
- In postmenopausal women not on estrogen replacement, or those
  with low estrogen states (e.g., Depo-Provera or Implanon users),
  estrogen cream helps maintain patency of the os. This is especially important if dilation was done for postsurgical (conization)
  scarring complications.

# CONCLUSION

Cervical stenosis may require cervical dilation several times on a monthly basis to keep the os patent. Pregnancy and vaginal delivery may actually lead to a more lasting cure. As long as the patient is menstruating and is asymptomatic, and a Pap smear can be obtained, then physician intervention is not needed.

# COLPOSCOPIC EXAMINATION

Gary R. Newkirk

Colposcopy is the examination of the cervix, vagina, and genital organs with light and magnification to identify abnormal areas for biopsy, so that the patient can be triaged to appropriate care. Topical application of saline, acetic acid, and iodine solutions helps identify biopsy sites.

Addressing the widespread human papillomavirus (HPV) and genital epithelial dysplasia epidemic requires mastery of the skills to perform colposcopy, cervical biopsy, and endocervical curettage (ECC). The most frequent indications for these procedures include evaluation of an abnormal Papanicolaou (Pap) smear (see Chapter 151, Pap Smear and Related Techniques for Cervical Cancer Screening), visible cervical abnormalities, evidence of clinical HPV infection, and follow-up of prior cervical treatment. Most cases of cervical dysplasia can be managed entirely in the outpatient setting. Successful colposcopy requires strict compliance with established protocol and often the support of the pathologist, urologist, and gynecologist. Mechanisms for excellent documentation and rigorous follow-up are mandatory. Physicians who assimilate colposcopy skills into their practices will respond to a major public health problem and enhance their patients' access to care.

The *colposcope* is essentially a stereoscopic, portable operating microscope (3× to 40×) with a focal distance appropriate to examine the genitalia and cervix. The colposcopic examination serves to (1) identify normal landmarks, (2) identify abnormal areas in relation to these landmarks, (3) facilitate directed biopsy of abnormal areas for histologic diagnosis, and (4) rule out invasive cancer. Based on the findings, patients are triaged for observation, for procedures (e.g., cryotherapy, loop electrosurgical excision procedure [LEEP], cervical cold conization), and for definitive staged therapy for invasive carcinoma.

Colposcopic-directed biopsy provides histologic clarification of abnormal Pap smears; this is mandatory before definitive therapy. Premalignant and malignant cervical conditions produce colposcopically identifiable epithelial changes that are often characteristic and generally occur within the transformation zone (TZ), which can be examined carefully during the colposcopic examination. Ultimately, the pathologist is the one who provides the histologic diagnoses for abnormalities identified during the colposcopic examination. Therefore, the major challenge for the colposcopist is to distinguish the normal from the abnormal and to sample the most abnormal-appearing changes for histologic confirmation. When there is any question about the colposcopic impression, biopsy should be undertaken. The ECC, or other cervical assessment methods such as endocervical brushing techniques, is performed as part of the routine colposcopic examination (contraindicated in pregnancy) to confirm the absence of occult disease in the endocervical canal. Nearly all agree that traditional ECC should be performed (1) if there is any question of invasive disease within the canal; (2) before ablative therapy such as cryotherapy or laser ablation; (3) as part of the work-up for

atypical glandular cell abnormalities; (4) when either the initial or follow-up cytology indicates a high-grade squamous intraepithelial lesion and colposcopy of the cervix does not yield a clear source; and (5) when the entire TZ/squamocolumnar junction (SCJ) cannot be evaluated (known as an "unsatisfactory colposcopy"). Other common reasons for performing a traditional ECC include follow-up of the treatment of severe dysplasia, especially when a cone resection (including LEEP) was performed and histology indicates positive margins with significant dysplasia, or if the ECC immediately after a cone resection was positive.

Colposcopy itself, without the benefit of histologic confirmation, is not considered a diagnostic tool. Even though colposcopically defined visual abnormalities correlate with cervical dysplasia or frank carcinoma, the ultimate diagnosis rests on the traditional histologic interpretation of submitted samples and not with the visual pattern recognition. Accordingly, diagnostic accuracy requires that the colposcopist perform *liberal* biopsy of the abnormal cervix.

In the past decade, major changes in our understanding of the epidemiology and science of cervical carcinoma have yielded efforts to develop a unified terminology to be used throughout the international scientific community. The International Federation for Cervical Pathology and Colposcopy (IFCPC) approved a basic colposcopic terminology at its 7th World Congress in Rome in May 1990 and further refined the terminology at its 11th World Congress in Barcelona, June 9, 2002 (Fig. 137-1). These terms should be used to describe findings during the colposcopic examination. Those terms marked with an asterisk are correlated with a higher likelihood of the histology demonstrating more severe dysplasia or cancer.

## **COLPOSCOPIC ANATOMY AND FINDINGS**

The prudent colposcopist must be completely familiar with the normal findings and the visual abnormalities that correlate with dysplasia and malignancy on the cervix. Basic Pap smear terminology and cervical anatomy are reviewed in Chapter 151, Pap Smear and Related Techniques for Cervical Cancer Screening. Colposcopy terminology is summarized in Figure 137-1. It is also important to consider the appearance of the cervix in different age groups because the anatomy varies developmentally in response to hormonal stimulation (Figs. 137-2 to 137-4).

# **Normal Colposcopic Findings**

See Figures 137-2 and 137-3.

# Original Squamous Epithelium

This is a featureless, smooth, pink epithelium on the outer aspects of the ectocervix going back to the cervicovaginal reflection. There are no features suggesting columnar epithelium, such as gland

#### Colposcopic Terminology\*

- I. Normal colposcopic findings

    - 6. Atypical vessels
- III. Colposcopically suspect invasive carcinoma
- IV. Unsatisfactory colposcopy
  - A. Squamocolumnar junction not visible
  - B. Severe inflammation or severe atrophy
  - C. Cervix not visible
  - D. Entire lesion not seen (i.e., goes into canal)
  - E. Most advanced lesion not sampled (i.e., in canal)
- V. Miscellaneous findings
  - A. Nonacetowhite micropapillary surface (micropapillomatosis vaginalis)
  - B. Exophytic condyloma
  - C. Inflammation
  - D. Atrophy
  - E. Ulcer
  - F. Other (polyp, hemorrhage, cysts, etc.)

Figure 137-1 Colposcopic terminology. \*See text for definitions. †For the effects of acetic acid and iodine to be appreciated, the cervical and vaginal tissues must have estrogen stimulation. (Adapted from Stafl A, Wilbanks GD: An international terminology of colposcopy: Report of the Nomenclature Committee of the International Federation of Cervical Pathology and Colposcopy. Obstet Gynecol 77:313–314, 1991.)

openings or nabothian cysts. The epithelium was "always" squamous and was not transformed from columnar to squamous after birth.

#### Columnar Epithelium

This is a single layer of mucus-producing, tall epithelium that extends between the endometrium and the cervical squamous epithelium. Columnar epithelium appears irregular, with stromal papillae and clefts. With acetic acid application and magnification, columnar epithelium has a grapelike or "sea anemone" appearance. It turns mildly acetowhite. Columnar epithelium is found in the endocervix, surrounding the cervical os, and is generally visible on the ectocervix in the reproductive age group.

#### Transformation Zone

As a woman ages, and under the influence of various hormones, the columnar epithelium that is originally found on the ectocervix is covered and transformed into squamous epithelium. The transformation zone is the geographic area between where the original squamous epithelium ended medially and where the outer lateral edge of the columnar epithelium currently exists. It is occupied by metaplastic epithelium in varying degrees of maturity because the columnar epithelium is being "transformed" into squamous epithelium. There is no way to discern where the original squamous epithelium was and

what has been transformed. What can be identified is the *active TZ*, which contains gland openings, nabothian cysts, and, typically, islands of columnar epithelium surrounded by metaplastic squamous epithelium. The recognizable TZ is the area of most active metaplasia and transformation. The *active TZ* then extends from the SCJ (see later) laterally to the outermost visible gland. For all practical purposes, when the term "transformation zone" is used, it is generally referring to the active TZ because that is where disease processes occur. The progression, then, from central to lateral, is columnar epithelium, SCJ, active TZ, squamous epithelium that has been transformed, and original squamous epithelium.

#### Squamous Metaplasia

Columnar epithelium on the ectocervix is transformed over time into mature squamous epithelium by undergoing squamous metaplasia. Squamous metaplasia typically occupies the TZ to varying degrees. Metaplasia appears as a "ghost white" film when acetic acid is applied and it looks like a denser line of this white where the columnar epithelium and squamous epithelium meet.

### **Squamocolumnar Junction**

Generally, this is a clinically visible line seen on the ectocervix or within the distal canal (e.g., postcryotherapy or in the

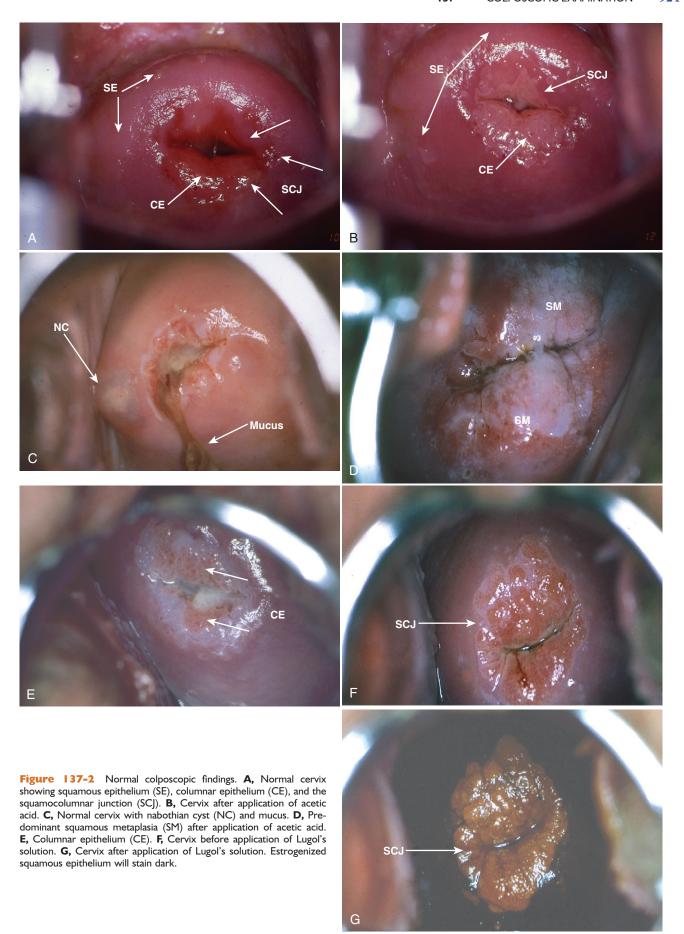

Figure 137-3 Normal colposcopic variants. A, Cervix with irregular contour due to birth trauma. SCJ, squamocolumnar junction. B, Pregnant cervix with mucus, thin, bluish epithelium, and metaplasia. C, SCJ unable to be seen (often encountered after treatment and in older patients). D, Prominent vessels can overlie nabothian cysts (NC), some of which may appear atypical. Biopsy is recommended if there is any doubt. AV, atypical vessel. E, Blue/green filter can enhance visualization of vessels, allowing the red vessels to appear black against a greenish background.

postmenopausal age group) that demarcates endocervical tissue from squamous tissue. Conceptually, the SCJ is comparable with the vermilion border around the mouth and the dentate or pectinate line in the rectum, where the mucosa meets squamous epithelium. The SCJ is the inner (medial) border of the TZ.

# **Abnormal Colposcopic Findings**

See Figure 137-4.

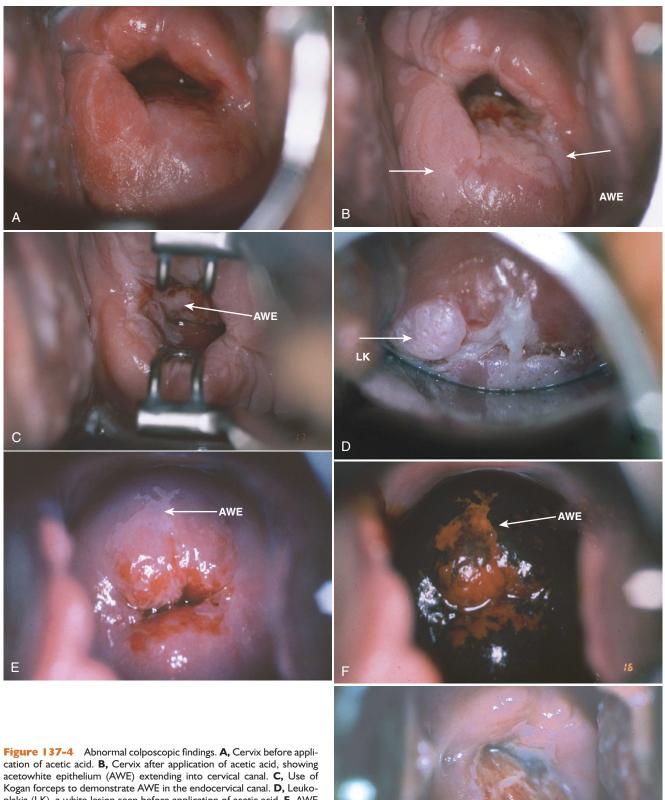

### **Atypical Transformation Zone**

A TZ with findings suggesting cervical dysplasia or neoplasia is considered abnormal. Usually, acetic acid (3% to 5% vinegar) is

applied and the cervix is viewed under magnification with the colposcope.

- 1. Acetowhite epithelium (AWE): Epithelium that transiently whitens after the application of acetic acid. Areas of acetowhite correlate with higher nuclear density. The white staining fades within minutes. The more abnormal the changes, the more quickly they will turn white, the more dense they will be, and the longer they will last. All AWE is not necessarily abnormal because metaplasia also has a higher nuclear ratio owing to a more rapid growth rate and turns white with acetic acid.
- Punctation: A stippled appearance of capillaries viewed end-on; often found within acetowhite areas, where they appear as fine to coarse red dots.

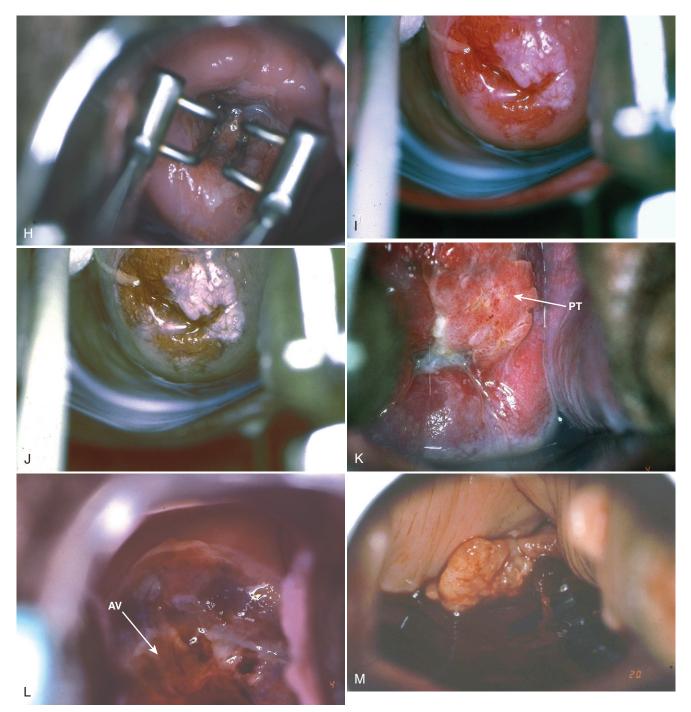

МО

Kogan forceps to demonstrate AWE in the endocervical canal. **D**, Leukoplakia (LK), a white lesion seen before application of acetic acid. **E**, AWE lesion before application of Lugol's solution. **F,** After application of Lugol's solution, the same AWE is now iodine negative. **G,** AWE with mosaic pattern (MO) and endocervical involvement.

Figure continues on following page

G

**Figure 137-4, cont. H,** AWE with endocervical involvement seen with Kogan endocervical dilators. **I,** AWE showing a coarse mosaic pattern before green light application. **J,** AWE showing a coarse mosaic pattern after green light application. **K,** Large, protruding lesion with coarse punctation (PT). **L,** Friable, peeling cervical epithelium and atypical vessels (AV) suspect for invasive carcinoma are seen in this example of invasive cervical carcinoma. **M,** Grossly deformed mass replacing the cervix consistent with invasive carcinoma.

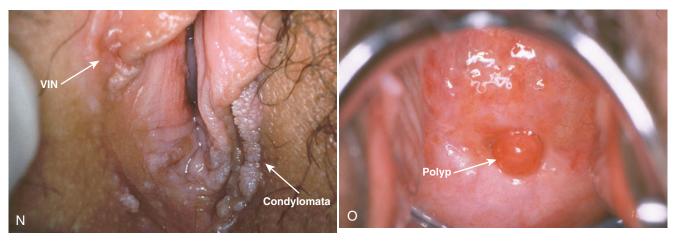

Figure 137-4, cont. N, Colposcopic view of the vulva with both condylomata and vulvar intraepithelial neoplasia (VIN). Remember, colposcopy includes inspection of the vulva. O, Central cervical polyp.

- 3. Mosaicism: An abnormal change made up of small red blood vessels appearing in linear form, suggesting a confluence of tile or chicken-wire patterns. This is best viewed after staining with acetic acid under magnification.
- 4. Leukoplakia (hyperkeratosis): Typically an elevated white plaque seen before the application of acetic acid. There is generally no change, or the area becomes more densely white, after application of acetic acid.
- 5. Abnormal blood vessels: Atypical, irregular, true vessels with abrupt courses and patterns; often appear as commas, corkscrews, or spaghetti-like shapes. No definite pattern is recognized, as there is with punctation or mosaicism. Abnormal blood vessels are seen in cancer and occasionally in advanced dysplasias.
- Iodine-negative epithelium: Estrogenized epithelium will stain with Lugol's solution to a deep brown color. Abnormal tissue and nonestrogenized tissue do not stain.

### Suspect Invasive Cancer

A complex pattern consisting of roughened, irregular cervical epithelium, typically with abundant abnormal vessel patterns and dense acetowhite change, often with a dense eggshell-white or slightly yellowish hue. It may also appear as ulcerated, friable, necrotic tissue. There may be a bulk effect or tumor-like appearance.

# **Unsatisfactory Colposcopy**

In an unsatisfactory colposcopy, the entire SCJ or the limits of all lesions cannot be completely visualized. Proper examination can also be hampered if an active inflammatory process is present, if the patient is not estrogen primed (e.g., postmenopausal without replacement therapy, on progesterone-only types of contraception, lactation), or if heavy menses is present.

# Other Colposcopic Findings

- Vaginocervicitis
- Traumatic erosion
- Atrophic epithelium
- Endocervical polyps
- Changes from diethylstilbestrol (DES)
- Abnormal pigmentation
- Nabothian cysts
- Post-traumatic clefts, deformities from birth or treatment
- Vaginal, vulvar, perineal, perianal lesions

Guidelines regarding visual colposcopic findings help ensure sampling of the most advanced sites of cervical dysplasia. The classic hallmark of cervical dysplasia includes the change that dysplastic epithelium undergoes after the application of 3% to 5% acetic acid (vinegar) or Lugol's (concentrated iodine) solution.

After the application of acetic acid to estrogenized tissue, dysplastic epithelium typically turns whiter than the surrounding normal epithelium (AWE). More advanced dysplasia typically appears more densely white, thicker, and smoother with raised borders. The surface of advanced dysplasia often becomes rougher or thicker as the severity of dysplasia advances and satellite lesions (multiple small abnormal areas) are less common. There may begin to be a "yellowish" hue. Changes in the vasculature pattern also correlate with cervical dysplasia. These abnormal patterns, which often occur in an acetowhite or leukoplakia patch, include punctation, mosaicism, and frankly abnormal vessel variations. The more coarse the punctation or mosaicism, the more severe the dysplasia is. Frankly abnormal vessel patterns imply severe dysplasia or potential invasive carcinoma.

After the application of Lugol's solution to estrogenized tissue, there is an immediate blackening (staining) of normal epithelium (iodine uptake is high in normal cells that are rich in cytologic glycogen). Abnormal dysplastic tissue, which has cells that contain much less intracellular glycogen, are not stained by iodine (Lugol's-negative epithelium) and remain white or faint yellow. The same pattern is seen if there is little or no estrogen stimulation.

Squamous metaplasia, a normal finding, may appear slightly acetowhite and may take up Lugol's solution incompletely; therefore, this tissue can cause some degree of confusion for the colposcopist. Squamous metaplasia is the physiologically normal tissue present where the columnar epithelium is being transformed into mature squamous epithelium. This occurs in the TZ—the same site where dysplasia generally occurs. Squamous metaplasia is especially prominent with certain conditions, such as active cervicitis, and where healing and reparative activities occur, such as after treatment. Questionable areas always warrant biopsy. If squamous metaplasia without dysplasia is reported on biopsy, but the Pap smear was abnormal, the prudent colposcopist must look elsewhere to explain the finding of dysplasia on the Pap smear (see Appendix K). A report of squamous metaplasia among other biopsies revealing dysplasia reflects the difficulty encountered by the colposcopist in evaluating this normal variant of acetowhite change. (Indeed, neither are all appendices removed for an acute abdomen the source of the pain!) The only other common areas that normally turn slightly white with acetic acid are the endocervical (columnar) cells, which are typically located in the cervical canal and extend a variable distance onto the exocervix. Endocervical tissue can usually be differentiated from abnormal areas by colposcopic examination because of its grapelike

appearance on high-power magnification. Biopsy is still warranted if there is any confusion.

This chapter focuses on the evaluation of the abnormal Pap smear as it typically relates to cervical disease. The complete examination also includes the colposcopic examination of the remainder of the genital system in women. The colposcope can also be used for other purposes, such as to examine male genitalia or the anus, and to evaluate sexual abuse victims (see Chapter 99, High-Resolution Anoscopy, Chapter 118, Androscopy, and Chapter 157, Treatment of the Adult Victim of Sexual Assault). Ultimately, the patient's cytologic, colposcopic, and histologic data are used in concert to direct appropriate management. A well-managed colposcopy program provides effective evaluation and treatment for all patients with identified abnormalities of the cervix and genital tract.

Many colposcopists keep their scopes immediately available to augment the routine Pap and pelvic examination, especially if abnormalities are seen and both time and patient preference are favorable. Although complete formal colposcopic examination and biopsy can be performed when visual abnormalities are identified, many clinicians prefer to reschedule patients for full colposcopic examination at a later date. This allows more time for patient education and thorough evaluation.

#### **INDICATIONS**

Refer to Appendix K for the 2006 American Society for Colposcopy and Cervical Pathology (ASCCP) Consensus Guidelines on the management of cytologic and histologic cervical abnormalities, and the indications and clinical scenarios in which colposcopy is indicated. The most common indications include the following:

- Pap smear consistent with dysplasia or cancer (see Chapter 151, Pap Smear and Related Techniques for Cervical Cancer Screening, for detailed recommendations regarding abnormal Pap smears)
- Pap smear with atypical glandular cells (always perform colposcopy)
- Worrisome history despite normal Pap smear findings (e.g., postcoital bleeding)
- An atypical Pap smear in which the patient tests positive for high-risk HPV
- Suspect visible lesion or palpable lesion of the cervix
- Abnormal vaginal bleeding, especially if postcoital, regardless of Pap smear status
- History of intrauterine DES exposure
- Evaluation or follow-up of previously treated or high-risk patients

The colposcope can be used for other reasons, such as removal of a cervical polyp, to find a lost intrauterine contraceptive device string, or to evaluate a rape victim, but in these instances a full colposcopic examination protocol is generally not indicated.

#### **CONTRAINDICATIONS**

There are no absolute contraindications to colposcopy. Most contraindications relate to temporary or treatable conditions that alter the timing of the colposcopic examination rather than absolutely prevent it from occurring. The satisfactory colposcopic examination requires excellent visualization with a compliant and cooperative patient.

#### **Relative**

- Active inflammatory cervicitis
- Uncooperative patient
- Heavy menses (may prevent adequate examination)

**NOTE:** Pregnancy is not a contraindication to colposcopy, including biopsy, although a slightly different protocol is used and more bleeding can be expected from the biopsies.

**Figure 137-5** A contemporary colposcopy suite with motorized table with leg stirrups, boom-mounted video colposcope, and available loop electrosurgical excision procedure unit.

# **EQUIPMENT AND SUPPLIES**

The equipment and supplies used during routine colposcopy should be within easy reach in the colposcopy examination room (Figs. 137-5 through 137-7).

- Colposcope: variable fixed-power or zoom lens (3x to 7x low power to 15x to 40x high power).
- Biopsy forceps\* (e.g., Tischler, baby Tischler, mini-Townsend, Kevorkian).
- Endocervical curette\* (Kevorkian, no basket).
- Endocervical speculum (Kogan, both narrow and wide types).
- Ring forceps.\*
- Tenaculum<sup>†</sup> (rarely used).
- Cervical hook<sup>†</sup> (rarely used).
- Pap smear materials.
- Vaginal speculums (e.g., metal Graves or disposable plastic speculum) in various sizes and lengths (use largest tolerated), or a clear, lighted, plastic speculum setup (e.g., Welch Allyn) for selected cases.
- Acetic acid solution 3% to 5% (white vinegar; 4 to 6 oz, or 120 to 180 mL).<sup>‡</sup>
- Full-strength Lugol's iodine solution (30 mL) (not always necessary after experience is gained but must be readily available).<sup>†,8</sup>
- Monsel's solution (ferric subsulfate), 1 mL. Monsel's is a topical astringent and is used to control bleeding after biopsy. It should be thoroughly shaken in its original bottle and then allowed to evaporate in a separate container until it is the consistency of a thick, yellowish-brown paste; this renders it a potent astringent to control biopsy-induced bleeding. Monsel's solution should be prepared several days in advance in order to achieve proper consistency. If the solution becomes too thick, it can be diluted with liquid solution from the original bottle.

<sup>\*</sup>Included in the "colpo pack." These must be sterilized before procedures. "No-touch" technique is used on the ends of instruments touching the patient. Reusable instruments are sterilized, but colposcopy is not a "sterile" procedure per se.

<sup>&</sup>lt;sup>†</sup>Available in colposcopy room but not used at every procedure.

Grocery store or mix to make 3% to 5% acetic acid.

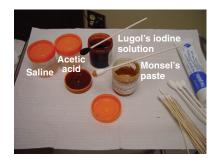

<sup>§</sup>Hospital pharmacy.

**Figure 137-6 A,** Narrow Kogan endocervical speculum. **B,** Kevorkian endocervical curette without basket. **C,** Tischler "wide jaw opening" biopsy forceps in both the large and small ("baby") options. **D,** A I-cm ring forceps used to apply vinegar with folded gauze or cotton balls, or assist in visualizing the vaginal fornices and manipulating the cervix. **E,** A small cervical hook and tenaculum to help move the cervix (rarely needed). **F,** Vaginal speculum with glove finger applied and used as vaginal wall retractor. **G,** Vaginal speculum with vaginal wall retractor inserted.

- Cotton- or rayon-tipped swabs (8 to 10)
- Junior scopettes/OB-GYN applicators (6 to 10)
- 4 × 4-inch gauze
- Urine or sputum cups for vinegar
- Vaginal sidewall retractor
- Underpads ("chuck pads") (17 × 24 inch)
- Cotton balls (15 to 20)
- Power-assisted patient examination table that can be raised or lowered (Minimum height should be no more than 24 inches from floor, or older and disabled patients will have a difficult time getting on to it.)

Optional items include a preprocedural dose of an oral nonsteroidal anti-inflammatory agent, aromatic ammonium capsules

**Figure 137-7** Common items on the colposcopy tray in addition to the equipment in Figure 137-6: cups of normal saline, acetic acid, Lugol's solution, Monsel's solution that has dehydrated to a paste, small and large swabs, lubricant. Formalin bottles and Pap smear supplies are not included here.

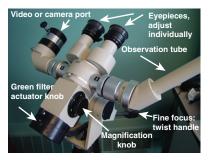

("smelling salts") for vasovagal responses, and a camera-video attachment.

Some clinicians now use a Pap smear sampling or similar brush to obtain the endocervical assessment instead of performing a formal ECC. Disposable ECC devices are also available and may be substituted for the reusable Kevorkian device.

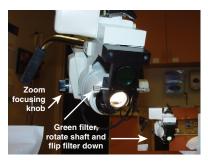

Colposcopes come in a variety of "shapes and sizes" (Figs. 137-8 through 137-11), but all are basically the same. The stand may be

**Figure 137-8** A pedestal-mounted colposcope with teaching head attached and fiberoptic light source.

**Figure 137-9** Features of the colposcopic head: fixed magnification knob, green filter knob, twisting handle for fine focus. Magnification changes are available between 4× and 25× in five steps. The camera/video port and observation (teaching) tube are optional features.

**Figure 137-10** A zoom power colposcope head with green filter and zoom focus knob. Magnification smoothly zooms from  $3\times$  to  $20\times$ .

a pedestal, may be on rollers, or may project out on an arm. There is a knob for changing magnification and another for fine focusing. The eyepieces also focus independently. A simple mechanism is usually available for inserting a *green filter* into the visual field, which makes identifying vascular abnormalities easier. The unit is turned on to the highest light intensity and then used essentially as a three-dimensional, short-range set of binoculars, but with an intense light source and variable magnification.

Some scopes have *video options* that project the image on a screen instead of using the binocular option (i.e., Welch Allyn; see Fig. 137-11). Most other scopes can be adapted for video use. In teaching situations, some type of video mode or teaching head adapter is mandatory. It is not necessary to take pictures or video for routine colposcopic examinations.

# PREPROCEDURE PATIENT EDUCATION AND FORMS

Providing educational materials to the patient and the patient's partner before the procedure can help alleviate the fear and uncertainty surrounding not only the procedure, but all of the issues surrounding HPV infection. Brochures are available from the American College of Obstetricians and Gynecologists (ACOG), ASCCP, and several other organizations (see the sample patient education handout online at www.expertconsult.com). An excellent patient education videotape is available from The National Procedures Institute (Midland, Mich). By providing materials beforehand, the clinician can focus on questions rather than try to take the time to explain a very complex topic with every patient.

- Discuss the indications for colposcopy with the patient. The patient should acknowledge the importance of long-term follow-up. The patient should advise the physician's clinic of change of address or telephone number.
- Instruct the patient to continue contraceptive practices before and
  after the colposcopic examination until treatment or management decisions have been made. There is no evidence that any
  type of contraception or estrogen replacement therapy causes
  progression of cervical dysplasia.
- Explain to the patient that a pregnancy test may be performed on the day of the procedure if pregnancy is a possibility, but colposcopy with or without biopsies carries very low risk in the pregnant woman. ECC is contraindicated in pregnancy.
- Instruct the patient to consume a regular diet on the day of the procedure and not to skip a meal before the procedure. This lessens the possibility of a vasovagal episode.
- Advise against taking aspirin, or medications containing aspirin, for
  7 days before the procedure. Aspirin consumption within the past
  week does not ordinarily contraindicate colposcopy with biopsy,
  but you should be aware of the potential for more bleeding. Normally, nonsteroidal anti-inflammatory drugs, such as ibuprofen,
  do not significantly prolong bleeding; therefore they may be taken
  before the procedure for pain control.
- Review the medical history with particular attention to in utero exposure to DES; drug allergies; asthma; diabetes mellitus; history of vagal sensitivity (frequent fainting); bleeding disorder; recent symptoms of cervicitis or pelvic inflammatory disease; symptoms or history suggesting pregnancy; symptomatology suggestive of an endometrial disorder that may require endometrial sampling; and history of prior cervical treatment, including conization, laser therapy, or cryotherapy. Latex or iodine allergy history would contraindicate the use of latex gloves or iodine-containing solutions (Lugol's or povidone-iodine).
- Explain that the procedure will take about 20 to 30 minutes. Most clinics ask patients to arrive at least 15 minutes early to allow for appropriate education, a pregnancy test, and questions.
- If pictures will be taken, inform the patient and establish consent before the actual procedure.

- Review the risks before the procedure: pain, infection, bleeding, discharge, and missed disease. Menstrual-type cramping and limited discharge are common, but persistent pain, bleeding, or infection is rare.
- Explain that colposcopy with biopsy ordinarily renders a diagnosis and is not a therapeutic procedure per se. Definitive therapy will be determined by correlation of historical, colposcopic, cytologic, and histologic data.
- Discuss treatment options. Ordinarily, cervical cryotherapy, if indicated, is performed after the cervix has had time to heal from the biopsy and pathology reports are available. This typically can be performed as early as 2 weeks after colposcopy or after the next menstrual cycle.
- If applicable, inform the patient that she will probably receive a separate bill for the interpretation of the pathology samples obtained during the biopsy procedure.
- Subacute bacterial endocarditis prophylaxis is not necessary.

#### **PROCEDURE**

Figure 137-12 includes forms for documenting the colposcopic examination for both initial and follow-up visits. Clinicians are also advised to either dictate or record their findings in the medical record to supplement the colposcopic examination form, if necessary.

In addition to the necessary technical skills, the successful colposcopy program requires close attention to data interpretation and careful patient follow-up. The patient who has an abnormal Pap smear and who ultimately has biopsy-confirmed cervical dysplasia remains at an increased lifetime risk for recurrence of genital malignancy.

- Prepare the colposcopy room. Make sure the room is warm. Some patients benefit from quiet background music. Have all necessary solutions and equipment ready at hand. Make sure the appropriate culture media, potassium hydroxide (KOH), and wet preparation materials are in the room. Keep all sizes of specula in your colposcopy room; prewarming is appreciated.
- Prepare the patient. Mail information before the procedure. Answer her questions. (See section on Preprocedure Patient Education.) Ibuprofen 800 mg may be offered 30 minutes before the procedure. Check for medication, latex, and iodine allergies.
- 3. Obtain informed consent. Before the office visit, allow the patient to review a written description of the procedure, its risks, and complications (see the sample patient education handout online at www.expertconsult.com). Address questions and concerns. Obtain informed consent, which should include a signed consent.
- 4. Obtain a pregnancy test as necessary. ECC is contraindicated in pregnancy. Unexpected early pregnancy at the time of colposcopy is common. Even if ECC is performed, it rarely, if ever, has any adverse consequence.
- 5. Perform a bimanual examination if one has not been done recently. If a Pap smear is to be collected/repeated, complete that before the bimanual examination. The bimanual examination can also be performed after the colposcopy, but it may be more difficult if biopsies are taken. Care should be taken not to traumatize the cervix. Is the uterus enlarged or tender? What position is the cervix? Can the cervix be moved? How long is the vagina? Are there palpated abnormalities of the introitus, vagina, fornices, or cervix? Examine the vulva for obvious condylomata.
- 6. Warm and insert the speculum. Colposcopy requires the widest speculum the patient can comfortably tolerate. The examination requires greater cervical and vaginal exposure than a screening Pap smear. Because of the relative duration of the colposcopic examination, the vaginal walls may migrate inward, which makes visualization more difficult. A carefully inserted,

- wide, large Graves speculum is far more comfortable in the long run than constant prodding and manipulating of the vagina to move the vagina out of the field of view if an inappropriately narrow speculum is used. If necessary, use a vaginal sidewall retractor. Alternatively, a surgical glove finger or condom can be stretched over the speculum blades and the end cut before insertion of the speculum to facilitate visualization. A thin layer of water-soluble vaginal lubricant can be applied on the speculum. This thin coating significantly facilitates the insertion and removal of the speculum and does not interfere with biopsy or Pap smear interpretation. Use both thumbscrew dimensions of the speculum to gain maximum exposure. Ideally, the colposcopic examination is facilitated by having the cervix facing anteriorly and virtually "suspended" between the blades of the speculum.
- 7. Grossly (using the naked eye) examine the cervix and vaginal fornices. Does the cervix appear inflamed or infected? An active cervicitis confuses colposcopic detail. Characterize the vaginal and cervical discharge. Are there areas of obvious vessel atypia? Scan the cervix for gross leukoplakia before applying acetic acid. Although acetic acid greatly enhances the elucidation of diseased areas, its mild vasoconstricting properties can render significant vessel detail less obvious. Use magnification to quickly scan the unstained cervix to identify landmarks, such as the TZ with its SCJ, and identify any possible abnormalities.
- 8. Obtain specimens for cultures, KOH and wet preparations, HPV DNA probe, and Pap smear, as necessary (see Chapter 142, Human Papillomavirus DNA Typing, Chapter 151, Pap Smear and Related Techniques for Cervical Cancer Screening, and Chapter 160, Wet Smear and KOH Preparation). Even a correctly performed Pap smear irritates the cervix, may cause bleeding, and may change fine colposcopic detail. The Pap smear may need to be repeated because the original Pap smear was performed at a different laboratory; because more than 3 months have elapsed since the last Pap smear; because the patient is pregnant (Pap smears are less reliable during pregnancy and because colposcopy is more difficult, it is important to maximize clinical assessment); and because of the need to allay any concern or confusion regarding the adequacy or interpretation of the original Pap smear results. Once the Pap smear, KOH, or wet preparation is obtained as deemed necessary, it is permissible to gently blot (not rub) excess secretions to view the cervix more clearly.
- 9. Apply 3% to 5% acetic acid. One method is to use 4 × 4 gauze rolled up tightly and held longitudinally in a ring forceps. This saturates the cervix with vinegar quickly and without trauma. Cotton balls or large swabs also work well. Use large swabs to repeat the application. Refer to acetic acid as "vinegar" or simply as "douche solution" when discussing it with the patient. Warn her of brief stinging and coldness. Repeat application as necessary, usually every few minutes because the changes fade rapidly.
- 10. Perform the colposcopic examination. Start with low power (typically 5×). Scan the entire cervix with bright white light. Use a vinegar-soaked, cotton-tipped swab to help manipulate the cervix and TZ into view. It is almost never necessary to use the tenaculum to move the cervix. The cervical hook can be used; however, it is rarely needed. The Kogan endocervical speculum aids in the examination of the distal endocervical canal. It should be used when either the entire SCJ or the entire lesion cannot be seen because it (or they) is inside the endocervical canal. Use this instrument gingerly to prevent bleeding and pain. (Proper application of the Kogan endocervical speculum, although generally not needed, requires skill and practice. Using it routinely, especially for those new to colposcopy, will assist in learning the technique for when it is needed.) Now use higher magnification to carefully document abnormal findings.

Figure 137-12, cont.

The entire TZ, including the SCJ, must be seen and evaluated. Abnormalities will usually turn white (AWE).

- 11. Use the green filter to enhance vascular detail. The green filter helps highlight vascular detail by rendering the red vascular patterns as black against a greenish background, similar to its use with the ophthalmoscope during the funduscopic examination. All abnormal areas require biopsy.
- 12. Consider the use of Lugol's solution. Lugol's solution aids with the identification of abnormal (dysplastic) areas, but its use is not

mandatory (it is unnecessary and messy). Both dysplastic and reparative (metaplastic) tissue will incompletely stain with concentrated iodine because of low levels of cellular glycogen (compared with the staining of healthy, mature squamous epithelium). The sharply outlined borders afforded by Lugol's staining can be dramatic, and this can help clarify biopsy sites. Iodine staining does not interfere with histologic investigation. However, Lugol's will obscure the underlying vascular pattern. Lugol's solution should be used when further clarification of potential

biopsy sites is necessary or when no lesion is seen with acetic acid. Applying Lugol's solution will also help delineate the SCJ for the beginning colposcopist (endocervical cells do not stain with Lugol's), and Lugol's solution is used for performing cervical loop electrosurgical procedures (LEEP, large loop excision of the TZ) because its effects last longer than those of acetic acid. Lugol's solution is also helpful in the examination of the vagina because acetowhite changes there can be more subtle.

- 13. Mentally map the cervix. The main goal of colposcopy is to identify areas for biopsy. The colposcopist must be able to differentiate normal tissues from abnormal. Tips on the findings include the following:
  - Acetowhite areas that are unifocal; have sharp, flat, straight borders; stain white quickly; and appear thick or raised are likely to be more abnormal histologically.
  - The presence of *coarse* punctation or mosaic patterns, or of frankly abnormal vessels, is associated with a more severe degree of dysplasia. Ultimately, however, the histopathologist is the one who makes the diagnosis from biopsy samples.

Be prepared to draw a careful record of what is observed and where biopsy samples were taken. The colposcopic impression of severity of disease *must be recorded* to compare and correlate later findings. Coppleson and associates (1986) proposed scoring indexes to help discern colposcopically identifiable lesions. Many physicians find these helpful when beginning colposcopy (Reid, 1993), but their utility and ability to predict the degree of disease present have been called into question.

- 14. Is the colposcopic examination satisfactory? The entire TZ, including all the SCJ, must be visualized. The borders of all lesions must be seen in their entirety (lesions should not disappear into the canal, for example). Patients who are uncooperative or who have a severely flexed uterus with inadequate visualization are potential "real-world" causes of unsatisfactory colposcopy. An unsatisfactory colposcopic examination coupled with cytologic evidence of significant dysplasia may necessitate a cervical conization for evaluation. It is a very important principle that all criteria be met to have an adequate examination. In summary, then, the satisfactory colposcopic examination requires the following:
  - Visualizing the entire TZ, including the SCJ
  - Identifying the area of abnormality producing the abnormal Pap smear
  - Confirming that the limits of all abnormal areas are clearly seen
  - Obtaining a biopsy sample of all abnormal areas
  - Verifying no colposcopic evidence of malignancy
- 15. Perform the ECC. Some colposcopists elect to omit ECC in instances where a clear source of cervical dysplasia is identified on the ectocervix, the SCJ is clearly seen, and the canal appears colposcopically clear of dysplasia. This is especially true if a low-grade squamous intraepithelial lesion (LGSIL) is the indication for colposcopy, the colposcopic examination supports cervical intraepithelial neoplasia (CIN) 1 or less, and visual inspection of the canal is negative. Others consider replacing ECC with careful endocervical brush sampling of the canal at the time of the colposcopic examination. Nonetheless, most colposcopists still perform ECC as a necessary component of the colposcopic examination, especially for a high-grade squamous intraepithelial lesion (HSIL) on a Pap smear, a marginally satisfactory colposcopy, a canal that is impossible or difficult to evaluate, suspicion of any degree of atypical adenomatous or glandular dysplasia, and always when ablative therapy such as cervical cryotherapy may be performed later (see Chapter 138, Cryotherapy of the Cervix, and Appendix K). Usually, neither local nor topical anesthesia is necessary.

Use a Kevorkian curette *without* a basket (or other appropriate curette). Insert gently until the internal cervical os is reached, about 1.5 to 2 cm within the canal. This can be man-

ifested by a slight puckering of the cervix with further advancement. In multiparous women the internal os is not well defined; the curette should not be advanced farther than 2 cm. Scrape the entire lining of the canal (360 degrees) *twice*. The procedure may be done with or without colposcopic observation. Use caution that the curette does not sample any tissue on the ectocervix and thus provide a false impression that there is disease within the canal. The curetted sample appears as a coagulum of mucus, blood, and small gray or tan tissue fragments. Sometimes a Cytobrush is used to retrieve the remnants of the ECC sample, which may persistently remain stuck in the canal. Submit the ECC sample in a separate bottle on a piece of paper towel, lens paper, or Telfa. Ordinarily, it is not necessary to place a sample pad in the posterior vaginal fornix, as it is with formal dilation and curettage.

Do *not* perform an ECC on pregnant patients or patients with evidence of active cervicitis or pelvic inflammatory disease. All other patients must have a documented negative ECC before ablative therapy.

Some physicians prefer to perform ECC after the cervical biopsy samples are obtained because (1) bleeding caused by the ECC can obscure lesions on the lower lip (but a cervical biopsy can bleed and "wash away" or dilute the curettage sample); and (2) the ECC, which takes only 30 seconds, is still the most uncomfortable part of the procedure. If performed first, however, the patient can be reassured early on that "the worst is over." Also, the chance of including dislodged tissue from a previous biopsy in the ECC specimen is minimized. This could again cause a false-positive ECC result, leading to more invasive treatment.

16. Obtain cervical biopsy samples. Sample the posterior (lower) areas first to prevent blood from dripping over future biopsy sites. Select the areas that appear most abnormal. "Blind random biopsies" are generally discouraged. The average number of biopsies taken is often in the range of two to five, but may be as few as one or as many as six or seven. It all depends on experience and the size, appearance, and number of lesions. The cervix can be manipulated with a cotton-tipped swab (preferred) or a hook (rarely) to provide an adequate angle for obtaining the biopsy sample. A 3-mm-deep sample is all that is necessary. It is not necessary to include normal-appearing tissue with biopsy samples (i.e., to include the margins of lesions in the sample). Beginning colposcopists can enhance their skills by placing samples from different biopsy sites in separate bottles and subsequently correlating them with colposcopic impression. After sufficient experience colposcopists can place all biopsy samples together. The cervix will be treated based on the most severe lesion as well as the size of the lesion. Putting different biopsies in separate containers only increases cost, but it does not change therapy. For anyone, to enhance the learning experience, an unusual or atypical-appearing lesion may be placed in a separate container to provide better feedback.

If bleeding is profuse from a particular site and more samples are needed, hold a cotton-tipped swab to the area and proceed with obtaining the next sample. (To control persistent bleeding, see the Complications section.) Do not apply Monsel's solution until all samples are obtained. Monsel's solution in a biopsy specimen can affect histologic interpretation. As noted previously, some physicians prefer to obtain the cervical biopsy samples before the ECC.

17. Apply Monsel's solution to bleeding areas after all biopsies have been obtained. To be most effective, the Monsel's solution should be as thick as toothpaste. This consistency can be achieved by allowing the solution to evaporate down to a pasty consistency. Once bleeding is controlled, swab out the excess Monsel's and bloody debris in the posterior vaginal vault, which appears as a black mass of coagulum that may alarm the patient when it appears as a black discharge and irritates the vulva. Observe the cervix until all evident bleeding ceases.

- 18. Examine the vagina while removing the speculum. Reapply acetic acid to the vaginal sidewalls. Gently retract the speculum with a back-and-forth twisting motion to the right and left and observe through the colposcope as the vaginal wall collapses around the receding blades. Are abnormal vaginal areas apparent? If there is any question, Lugol's solution may help clarify the situation because condylomata and dysplasia (vaginal intraepithelial neoplasia [VAIN]) do not stain. Be sure to colposcopically examine any vaginal areas that felt abnormal during the bimanual examination. Biopsies of the vagina can be obtained with the same biopsy forceps but are placed in separate containers. It is not necessary to take deep bites.
- 19. Examine the vulva and anus. Acetic acid application will produce an acetowhite effect in most sites with condylomata or dysplasia (vulvar intraepithelial neoplasia [VIN]). It is mandatory to do a careful vulvar colposcopic examination with acetic acid in these women who are at high risk for vulvar dysplasia, especially those with unexplained vulvar itching or other symptoms, smokers older than 40 years of age, those with abnormal-appearing areas of vulvar tissue, and those with human immunodeficiency virus infection.

The easiest way to examine the vulva is to begin superiorly. Use two hands to separate the vulva and slowly raise the power table with the foot pedal. Examine carefully from clitoris to anus. The finding of perianal condylomata warrants anoscopy, especially if they have been persistent. The Ives slotted anoscope is ideal (see Chapter 98, Anoscopy). If condylomata are grossly visible, it may be best to resolve the external lesions first before inserting the anoscope and risking spread internally. Acetic acid can be used in the anal canal but is rarely necessary. Small anal canal condylomata can usually be palpated. For the technique for sampling the vulva, see Chapter 159, Vulvar Biopsy. For high-resolution anoscopy, which is a colposcopic examination of the anal area, see Chapter 99, High-Resolution Anoscopy.

- 20. Allow the patient to recover. Have the patient rest supine for at least several minutes, then sit up slowly and rest again. Offer juice or cookies, especially if the patient has a history of syncope or missed the meal before her colposcopy.
- 21. Document your findings. Carefully draw a picture of lesions and biopsy sites. Photographs of the cervix do not replace accurately drawn diagrams of the colposcopic cervical findings. These should be included regardless of whether the colposcopic examination is considered adequate.

Chart whether the colposcopic impression supports outpatient cervical cryotherapy or if excisional treatment will be needed, and which cryotip or loop electrode should be used (size and shape). This is not a decision based solely on colposcopic appearance. It requires correlation of cytologic, colposcopic, and histologic data to define the appropriate therapeutic intervention. Factors such as lesion location, grade of dysplasia, and number and size of lesions also dictate treatment options. For instance, large lesions (>25 mm in diameter, >15 mm from the os, or involving more than two cervical quadrants), even if they are only mildly dysplastic, are treated more appropriately with loop excision or laser therapy, as opposed to a small focal severe dysplasia, which may respond to ambulatory cryotherapy very well. (See Chapter 138, Cryotherapy of the Cervix, and Chapter 149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia.) In general, the patient is a candidate for ablative therapy if the colposcopy is adequate (see earlier) and the following criteria are met:

- No lesion extends more than 5 mm into the canal
- The ECC is negative
- There is no colposcopic evidence of malignancy
- Any high-grade lesion is only focal in size (<1 cm)
- There is correlation between the Pap smear findings, the colposcopic impression, and histology

22. Discuss the findings and give postprocedure instructions. After the patient has recovered and is dressed, review your impressions but withhold the specific diagnosis until the histology report has returned and all the clinical data have been examined. Provide careful postprocedure instructions (see the sample patient education handout online at www.expertconsult.com). Advise abstaining from intercourse for 24 hours and using tampons for 5 days. Instruct the patient to return if she experiences unusual vaginal odor, discharge, pelvic pain, or fever. Make a specific agreement as to how the results of the biopsy are to be reported. Unless a problem arises, the patient does not need a follow-up pelvic examination. Discussing the results of the biopsy sampling and subsequent treatment options on the telephone may be an appropriate follow-up mechanism for some patients; however, most will appreciate a visit to the physician for this important interaction.

#### SAMPLE OPERATIVE NOTE

A prepared colposcopy procedure form, including patient identification materials, history, and a written diagram of findings, is an excellent way to document and archive findings (see Fig. 137-12).

#### **COMMON ERRORS**

- 1. Losing track of patients who have a significantly abnormal Pap smear or biopsy-proven dysplasia, and for whom treatment is necessary. This can place the patients at risk for delayed management and treatment. "No-shows" are a significant problem. Develop a follow-up tracking system.
- 2. Finding an abnormal-appearing cervix on visual inspection when obtaining a Pap smear but then relying on the Pap result to determine if colposcopy is needed. Visual abnormalities take precedence over the Pap report as an indication for colposcopy. If the cervix appears to be abnormal, colposcopy with biopsy is indicated.
- Omitting the ECC in patients for whom cervical ablative treatment may be an option, especially for high-grade dysplasia (see Chapter 138, Cryotherapy of the Cervix).
- Failing to inspect the vulva, cervical fornices, and vagina during colposcopy. Significant dysplasia can be a comorbid condition to cervical disease.
- Performing too few biopsies, especially for large, high-grade appearing lesions where there is risk of missing invasive cancer. Studies continue to emphasize the importance of obtaining enough biopsies.
- Canceling colposcopy in women who are having routine menses. Colposcopy can be performed in most patients regardless of bleeding.
- 7. Trying to perform colposcopy with an active cervicitis. Culture and reschedule soon.
- 8. Failing to take the time to address all the emotional issues surrounding HPV and other sexually transmitted infections, and condylomata/abnormal Pap smear concerns.
- Putting biopsies in separate formalin containers. This usually is not necessary.

#### **COMPLICATIONS**

• Bleeding. Most biopsy or ECC bleeding is minimal and handled readily with Monsel's solution. Rarely, the patient experiences a fresh, bloody discharge. Often, a simple reapplication of Monsel's solution is all that is necessary. Silver nitrate sticks may also be used to cauterize small areas of bleeding (see Chapter 40, Topical Hemostatic Agents). Some clinicians will saturate the end of a vaginal tampon with Monsel's solution and insert this to provide pressure and astringent action for persistent cervical oozing. The tampon can then be removed several hours later by the patient. Very rarely, a simple stitch of 4-0 absorbable suture across a particularly deep biopsy site may be required. At times, it may be

necessary to *cauterize* the biopsy site. An effective way to control fairly brisk bleeding is to *inject 1 to 2 mL of 2% lidocaine with epinephrine* into the bleeding site. This will either stop or reduce the bleeding enough to effectively apply Monsel's solution or cauterize the site. Use a needle extender (see Chapter 149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia) or a spinal needle to reach the cervix. If possible, try to avoid obtaining a cervical biopsy sample immediately before the menses; subsequent bleeding may be confused with menstrual flow. This may not be very practical in the busy daily routines.

- A foul cervical discharge, fever, or pelvic pain may indicate postprocedure infection. Infection is almost unheard of, but typically occurs on the third or fourth day after the biopsy sample has been taken. A cervical biopsy should be avoided if there is clinical evidence of significant, extensive cervicitis identified by erythematous changes and marked friability. Not only will pathology be more difficult to interpret, but bleeding can be quite brisk.
- Despite correct technique, there is the potential risk that the most advanced cervical disease may be missed by the colposcopist at the time of the biopsy sampling or potentially by the histologist at the time of tissue analysis. Careful, timely transport of all samples to a reputable laboratory is important. The ECC sample should remain separate from cervical biopsies. The colposcopist is well advised to be liberal in obtaining biopsies of all abnormalappearing areas of the cervix for histologic interpretation; costs can be controlled by placing all biopsies in one container. Widespread, four-quadrant cervical disease challenges the colposcopist to identify areas most likely to contain cervical carcinoma. Lack of correlation between the Pap cytologic results and subsequent histologic findings can suggest a situation in which potentially the worst area has not been sampled. The main goal of colposcopy is to rule out invasive cervical cancer and to select patients who are candidates for outpatient treatment. When the colposcopist cannot safely accomplish this goal, cervical conization—rarely, but importantly—is the only way of accomplishing this task. "Blind biopsies" in which random samples are obtained are, again, generally discouraged.
- Some women will experience vaginal discharge that often looks like coffee grounds after a cervical biopsy sample is obtained. This will typically last 1 or 2 days and should diminish with time. It is often due to the Monsel's solution used to control bleeding.
- Cervical biopsy sampling typically causes brief pain and discomfort.
   Ordinarily, this pain is well tolerated by most women. Careful explanation of the procedure, a warm room, and a caring, careful manner all minimize the discomfort. Studies have shown preoperative oral nonsteroidal anti-inflammatory drugs decrease discomfort associated with the procedure. Topical anesthetics generally are not left on long enough to make any difference.
- Rarely, vasovagal reactions occur with the procedure but are much more likely to occur with cervical cryotherapy.

# POSTPROCEDURE PATIENT EDUCATION

See the sample patient education handout online at www.expert-consult.com.

- Agree on a time to discuss and interpret biopsy findings by phone or follow-up visit.
- Explain that mild vaginal discharge may occur after a cervical biopsy procedure, especially if Monsel's solution was used to control bleeding. This discharge is often grainy and black, like coffee grounds, which is the result of Monsel's solution mixing with mucus and blood. This discharge may last approximately 24 hours.
- Advise the patient that she may have spotting for at least 48 hours. Although there may be some spotting, it is safe to resume intercourse after 24 to 48 hours.

- Instruct the patient to report passage of clots, onset of fresh, profuse bleeding, foul vaginal odor, fever, or pelvic pain. Women with these complaints after a cervical biopsy procedure require evaluation
- Encourage the patient to continue contraception.
- Patients rarely require vaginal creams after a cervical biopsy has been obtained. Nonetheless, some women may have vaginitis caused by organisms such as yeast, bacteria, or *Trichomonas*, and therapy aimed at these pathogens may be helpful and is not contraindicated after biopsy.
- Emphasize the importance of returning for definitive therapy. Reemphasize the relationship of cervical dysplasia with sexually transmissible disease, poor diet, smoking, and nonmonogamous sexual practices. Be sure the patient understands the lifelong risks of HPV infection.

#### INTERPRETATION OF RESULTS

If at all possible, the same pathologist (or at least the same group of pathologists) should interpret both the cytologic and histologic results for a given patient. The clinician should be concerned if a significant discrepancy is found between the Pap smear cytology, the colposcopic appearance of the cervix, and the biopsy histology. In general, a report that a more advanced lesion was found on the biopsy compared with the Pap smear (e.g., Pap = CIN 2; biopsy = CIN 3) is common and acceptable. The clinician should be concerned, however, if biopsy-generated histology results are significantly less advanced than the Pap cytology. In general, most will accept a biopsy diagnosis one degree less, but if it is two degrees, the discrepancy must be explained. For instance, a cytology smear indicating carcinoma in situ, with biopsy samples of only mild dysplasia, might indicate that the worst area was missed on evaluation and that the patient may have in situ or invasive carcinoma in another site. The clinician is advised not to freeze or ablate any cervix until the discrepancy between histology and cytology has been explained adequately and sufficiently. Repeating colposcopy with biopsy to reconcile the difference is indicated. Freezing invasive cancer is never acceptable.

A negative ECC sample will show strips or fragments of orderly, benign columnar epithelium with mucus and blood. Lack of identifiable endocervical tissue constitutes an inadequate ECC sample. An inadequate ECC sample is not uncommon, and in the overwhelming majority of patients it simply means that the ECC must be repeated before definitive ablative therapy. If the ECC sample indicates dysplasia, it is a positive ECC and an indication for an excisional procedure (see Chapter 134, Cervical Conization, and Chapter 149, Loop Electrosurgical Excision Procedure for Treating Cervical Intraepithelial Neoplasia). Current protocol does not support freezing the canal with a long, narrow probe to treat endocervical dysplasia. Some "positive" ECCs result from contamination with dysplastic lesions at the verge of the os. Nonetheless, do not assume this! The beginning colposcopist must remain comfortable referring patients with equivocal or problematic colposcopic, cytologic, and histologic correlation. Know your limitations and seek help.

# CRYOTHERAPY OF THE CERVIX

Madeline R. Lewis • John L. Pfenninger

Cryotherapy is the treatment of choice for select small cervical intraepithelial lesions (cervical intraepithelial neoplasia [CIN] 1, 2, and 3, or mild, moderate, and severe dysplasia). This procedure is easy to learn, is well tolerated by the patient, and has a success rate similar to other therapies, including LEEP (the large loop electrical excision procedure) and laser. It requires a refrigerant gas under pressure, such as nitrous oxide, and an applicator probe. The cryoprobe allows rapid freezing of cervical tissue, causing a controlled destruction of the transformation zone and the epithelial lesion. Cellular destruction is greatest when a rapid freeze, slow thaw, and refreeze method is used. This efficacious procedure has few complications, can be performed quickly, is low in cost, and preserves cervical tissue.

The *only negative aspect* is that there is no tissue specimen available to confirm removal of all abnormalities. However, considering that up to 18% of patients experience pregnancy complications after LEEP, cryotherapy should be strongly considered for women who meet the criteria for treatment.

Cryotherapy treats cervical dysplasia by destroying the lesion and the transformation zone. Cell death occurs as a result of ice crystal penetration into the intracellular space. The depth of destruction is directly proportional to the lateral spread of the freeze, which is measured by the size of the ice ball that forms around the tip of the cryoprobe. An ice ball of 5 to 7 mm will result in adequate cellular destruction, because severe dysplasia (CIN 3) can extend to a depth of 3 to 5 mm into the glands in the transformation zone. The frequency and depth of gland involvement seem to be directly proportional to the grade of the squamous intraepithelial lesion. However, the overall success of cryotherapy is related more to the size of the lesion than the grade of the lesion. Small high-grade lesions (<1 cm) may be adequately treated with cryotherapy. Low-grade lesions should be less than 3 cm in diameter (some recommend <2 cm). For all lesions, they should involve no more than two quadrants of the cervix and extend no more than 5 mm into the endocervical canal. Large high-grade lesions (>1 cm), microinvasive lesions, and invasive lesions need more aggressive treatment such as LEEP, conization, or even hysterectomy.

Treatment failures may occur with cryotherapy as with any other treatment modality. "Cure rates" have been in the 95% range for CIN 1 and CIN 2, which is consistent with other modalities. For CIN 3 the cure rate drops to 89% overall, but this has been correlated more to lesion size and depth, not to severity of disease. Highgrade lesions are often larger and extend deeper into the glands, making them more difficult to treat.

#### **ANATOMY**

Cervical anatomy is discussed in detail in Chapter 137, Colposcopic Examination.

# **INDICATIONS**

Also see the current American Society for Colposcopy and Cervical Pathology recommendations in Appendix K.

Cryotherapy may be used for treatment of squamous dysplasia that was confirmed with a biopsy after a complete and adequate colposcopic examination and if all criteria noted later have been met. It is essential that the Pap smear results, the appearance of the cervix on colposcopic examination, and the histologic report from the biopsy do not vary by more than one degree of severity. That is, colposcopic impression and histologic findings can only be one degree less severe than the Pap smear findings. If there is lack of correlation, this must be resolved or a LEEP or conization of the cervix is indicated because it is presumed the most advanced lesion has not been identified. It is common for histology to be worse than the Pap smear because the Pap smear is a screening test only. However, the Pap smear is essentially never two grades worse than tissue pathology or biopsy. If the correlation principle is met, the patient would then be treated based on biopsy findings. Cryotherapy may be used to treat low-grade squamous intraepithelial lesions (LSILs) and small, focal high-grade intraepithelial lesions (HSILs). Large high-grade lesions usually have deeper gland involvement, and these patients will need to have an excisional treatment, such as LEEP or conization. Cryotherapy is not appropriate for any invasive lesion. The practitioner must be sure to differentiate between "carcinoma in situ" and "microinvasive cancer." Although select patients with carcinoma in situ who meet the criteria may be treated with cryotherapy, microinvasive lesions should never be treated this way. Patients with microinvasive disease need a conization procedure to determine the true extent of the disease.

Criteria for cryotherapy of the cervix include the following:

- Complete colposcopic examination with good correlation between Pap smear results, visual examination, and histologic biopsy report.
- Entire squamocolumnar junction and the entire lesion must be visible ("adequate colposcopy").
- Lesions should be less than 2 to 3 cm in diameter and involve no more than two quadrants of the cervix.
- The probe tip must be able to cover the entire lesion and the entire transformation zone.
- The lesion does not extend more than 5 mm into the endocervical canal.
- The endocervical canal sampling is negative for dysplasia.
- The cervix should be relatively flat without large crevices.
- There should be no significant glandular involvement on biopsy.
- The patient must be reliable for follow-up.

Cryotherapy may also be useful to treat patients with chronic cervicitis that is culture negative and unresponsive to antibiotic therapy, and has negative colposcopy and biopsy findings. External genital human papillomavirus lesions may be treated with cryotherapy, although a different freezing technique is used (see Chapter 14, Cryosurgery, and Chapter 155, Treatment of Noncervical Condylomata Acuminata).

## **CONTRAINDICATIONS**

#### **Absolute**

- Patients with colposcopic or histologic findings more than one degree less severe than the Pap smear findings. These patients need to have a complete reevaluation before any treatment (see previous discussion).
- Positive endocervical curettage or other canal sampling that is positive (dysplasia or cancer).
- Large lesion that the cryoprobe will not cover completely.
- Lesion extends into the endocervical canal more than 5 mm.
- Large high-grade lesions or carcinoma in situ (>1 cm). LEEP is the treatment of choice for most of these lesions and will result in a better cure rate than cryotherapy.
- Invasive lesions (including microinvasion); these will need more aggressive treatment.
- Pregnancy.
- Cryoglobulinemia.
- Significant glandular involvement on endocervical curettage or biopsy.

#### **Relative**

- Patient is within 1 week of menses or is having heavy menstrual flow. The resulting canal edema from cryotherapy could obstruct the normal menstrual outflow.
- Acute cervicitis. In these patients it is best to treat the acute infection before cryotherapy.
- Immunosuppressed patients.
- Women exposed to diethylstilbestrol (DES) in utero, because they are at greater risk for cervical stenosis.
- Markedly irregular cervix where the indentations are deep and the cryoprobe will not reach these areas.
- Noncompliant patient (consider doing definitive excisional procedure).

Many would suggest that all CIN III lesions (i.e., carcinoma in situ) be treated with conization procedures. However, the data strongly support the efficacy of properly performed cryotherapy for small lesions that meet the aforementioned criteria. Cryotherapy is much more cost effective, with potentially fewer and less significant complications.

**Figure 138-1** Nitrous oxide tank with the yoke adapter for the cryogun. Several cryotips are attached.

Figure 138-2 Close-up views of yoke adapter with pressure gauge, cryogun, and cryotips. (Courtesy of Wallach Surgical Devices, Milford, Conn.)

# **EQUIPMENT AND SUPPLIES**

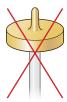

- Nitrous oxide 20-lb tank with a pressure gauge and gas cut-off valve (Figs. 138-1 and 138-2).
- Flexible tubing from tank to probe.
- Probe handle.
- Probe tips: 19- and 25-mm-diameter tips, slightly coned or flat; do not use any tips with nipples that are more than 5 mm in length (Fig. 138-3).
